### Abstract

The CLAS12 Data Acquisition System was designed and built as part of the CLAS12 detector project in Hall B at Jefferson Laboratory. This article contains a full description of the system, including requirements, design, hardware, and software descriptions, as well as the achieved performance. The associated computing, network, and slow controls systems are also described.

50

### 1. Overview

The CLAS12 Data Acquisition system (DAQ) collects data from the CLAS12 detector [1]. It is a networkbased system obtaining data from more than 100 front-

<sup>5</sup> end components comprising the trigger system signals, assembling the component data into events, monitoring data quality, and recording data to tape. Typical event rates are 15-30 kHz and 500-1000 MByte/s with an acquisition livetime above 90%. The CLAS12 DAQ

<sup>10</sup> software is written in C/C++ as an expandable multithreaded system, allowing relatively easy upgrades in case higher performance is required or new components have to be included into the system. The CLAS12 DAQ has been successfully operated during the first year of

the CLAS12 experiment and expected to be used in the future with only minor modifications.

## 2. Requirements

The CLAS12 DAQ requirements were initially defined for electroproduction experiments with a 10 kHz event rate and a 100 MB/s data rate, with livetime above 90%. During detector construction the data rate requirement was increased to 200 MB/s. The data rate requirements were never officially changed, however the very first experiment showed that the initial design requirements were too low. This situation was anticipated by

the developers and the system has been shown to be able to take data with an event rate of at least 30 kHz and a 55 data rate of at least 1 GB/s, which meets the current experiment demand. The system has the potential for further performance increases as well.

# 3. Design

The CLAS12 DAQ was designed as a pipelined, network-based system. The data-taking process starts from the front-end components. Those components can have different hardware and software implementations, but have to follow certain requirements to be compatible with the rest of the system. Front-end components are usually referenced as Readout Controllers (ROCs), although initially that term was used to name only the processing part of the front-end hardware and the corresponding software (for example Intel-based VME controllers). Currently, the ROCs used are commercial VME/VXS crates with Intel-based controllers and custom VME/VXS boards, commercial Linux servers, and Jefferson Laboratory(JLab)-designed VXS Trigger Processor boards (VTPs). VTPs are installed in all of the VXS crates, but they are read out by the DAQ as independent ROCs. All components receive a common 250 MHz clock distributed over OM3-rated parallel optic fibers. The same fiber system is used to distribute both the synchronization reset and trigger signals and to collect the busy signals from all front-end electronics.

All front-end components are connected via TCP sockets over Ethernet to the Event Builder (EB) component. The EB is a multi-threaded program (C applica-

Preprint submitted to Nuclear Instruments and Methods A

tion) running on a multi-core Linux server. Most frontend connections are 1 Gb links. However, for several components that generate significant data rate, a 10 Gb Ethernet connection is used.

- <sup>60</sup> The built events are output to the Event Transfer (ET) system. This multi-threaded program (C application) provides access to shared memory storage in a ring architecture where multiple data processing programs can be attached to process, filter, or monitor data quality on-
- line. The ET system is typically run on the same server as the EB, but it can also be used to distribute events to a sequential chain of ET servers to increase the aggregate data processing power.

The last component in the data chain is the Event 95

- Recorder (ER). This multi-threaded program receives data from the ET system and records it to the disk. A multi-stream mode is available, which allows several files to be written in parallel to the same or different disk partitions to increase writing performance. The event
- order in multi-stream mode is preserved. The CLAS12 DAQ system diagram is shown in Fig. 1.

Figure 1: Diagram of the CLAS12 Data Acquisition system. It includes 69 VXS/VME64X crates with front-end electronics, trigger modules, and Intel-based controllers running Linux OS. The backend components such as the Event Builder, Event Transfer, Event Recorder, and Run Control, run on a designated server (not shown) connected to the front-end crates by 1 Gb and 10 Gb Ethernet links.

# 4. Hardware Components

### 4.1. General Information

80

Most of the front-end electronics for the CLAS12 DAQ System was designed at JLab (except for the CAEN v1190/v1290 TDCs). The new modules take advantage of the higher performance and elegant backplane connectivity of the VITA 41 standard or "VXS", defined as VME with serial extensions. VXS was selected as the 12 GeV data acquisition backplane foundation for the front-end detector readout and trigger hardware interface because this standard not only supported legacy VME hardware but also offered a method to easily synchronize and pass signals between each of the payload slots to a central switch fabric slot. At JLab a dual-star configuration is used for the serial backplane. One switch slot is used for the trigger processing from the payload boards, and a second switch slot is used to distribute the essential timing and synchronization signals to each of the front-end boards.

The following VXS modules were produced: TS (Trigger Supervisor), TD (Trigger Distribution), TI (Trigger Interface), SD (Signal Distribution), FADC250 Flash ADC), DCRB (Drift Chamber Readout Board), VSCM (VXS Silicon Readout), SSP (Subsystem Processor), and VTP (VXS Trigger Processor). The SSP and VTP modules were designed for the CLAS12 Trigger system but eventually served for both the Trigger and DAQ systems.

Each of these VXS modules is described in detail in this section, except for the description of the VTP, which can be found in the CLAS12 Trigger System publication (see Ref. [2]). The VTP is installed in the VXS switch slot and manages the high-speed gigabit signaling from each of the payload slots, where eight differential pairs connect from the payload slots to the switch slots. The VXS crates used at JLab are manufactured by WIENER and the backplane can support up to 8 Gb/s. The payload boards use Xilinx FPGAs and have up to 10 Gbps transceivers. The payload boards are designed to run these high-speed gigabit transceivers at a maximum of 5 Gbps to transfer trigger data to the VTP module to produce the Level 1 trigger decision.

The design challenges for the reliable and successful transmission of gigabit serial data over the VXS backplane requires an investment in high-speed circuit board layout and routing tools. The FPGA selection requirements include at least four full duplex gigabit transceivers, with a user I/O pin count >500, and fast integrated block memory with multi-rate FIFO logic. We use the circuit board routing simulation Hyperlynx tools from Mentor Graphics [3], which are invaluable for critical simulation and verification of circuit board signal integrity for the gigabit transmission paths before the manufacturing process. The FPGA devices that we use are capable of 6.25 Gb/s serial transfer, and we have designed our circuit boards with signal integrity techniques using standard FR4 circuit board material to

120

125

achieve >2.5 Gb/s, which meets the data transfer bandwidth requirements.

135

Another significant investment required for the hardware verification of the gigabit transceivers was a digital signal analyzer with 8 GHz bandwidth to measure and record the backplane and fiber optic gigabit transceiver

- <sup>140</sup> performance and to perform jitter analysis on the critical system clock and synchronization signals with at least 1 ps resolution. We used the Tektronix jitter analysis software, which is a critical tool for the verification of our system clock, and for measurements of the
- <sup>145</sup> phase-controlled jitter attenuated clock provided by the Signal Distribution (SD) switch card in every crate. The investment of firmware development tools from FPGA industry leaders Xilinx and Altera were also taken into consideration for the upgrade path to VXS. We use the
- 150 Xilinx Aurora protocol for serial transmission as it is robust and simple, and is included with the FPGA development tools.

### 4.2. Fiber Optic Trigger Distribution System

As shown in Fig. 2, the trigger information from each VTP in the front-end crate, and the distribution of the global clock, synchronization, and trigger commands from the global trigger hardware, use a separate fiber optic cable. The crate sum fiber link is shown in orange, and the critical timing signals distributed to each front-

- end crate are blue. Each fiber optic link makes use of the Avago POP4 fiber optic transceivers and parallel OM3rated glass fiber cable with MTP connections. These fiber optic transceivers operate at 3.125 Gb/s for an aggregate bandwidth of 10 Gb/s, which is ample enough
- for the summing information that is sent forward to the global trigger processing hardware. The fiber link used for the distribution of the global clock, critical timing signals, and trigger commands runs at 1.25 Gb/s.

### 4.3. VXS/VME Crates

- <sup>170</sup> Previous experiments with the original CLAS spectrometer (see [4]) used the VXI standard, which was a new extension of the original VME standard. VXI offered a method to distribute the clock and other timing signals with low skews via the backplane. 9U circuit
- <sup>175</sup> boards were used that offered a large number of front panel input/output connections to handle the six sectors of the CLAS detectors that contributed to the Level 1 <sup>195</sup> trigger. The detector signals were digitized with FAST-BUS ADC and TDC modules, or in some instances, from VME or even CAMAC modules.
- During the initial design phase of the 12 GeV experiments at JLab, the requirements of a 200 kHz sustained 200

Figure 2: Hardware diagram with the implemented fiber links scheme. All critical signals such as CLOCK, SYNC, TRIGGER, and BUSY are distributed over optical fibers.

trigger rate demanded that the front-end modules adopt a new method of handling precision timing and synchronization over dozens of front-end crates. The latest technology at the 12 GeV inception included FPGA devices with high-speed serial transceivers built into the silicon fabric. A new VME extension was also emerging at the same time, which was labeled VXS, and defined a new high-speed gigabit connector with links between the VME slots and eight serial links to common switch slots. The VXS standard was declared as VITA 41 and several new standards have emerged in the past decade that expand the use of gigabit serial transmission via the crate backplane. For the JLab 12 GeV experiment era, we now have thousands of custom VXS payload and switch slot modules and hundreds of VXS front-end crates. Complex experiments and high-channel-count detectors make use of these custom VXS board designs for all four experimental halls at JLab.

### 4.4. VME Crate Controllers

The high-speed data physics acquisition and trigger systems for the JLab 12 GeV experiments have been standardized on the VME64X and VXS backplane and

245

250

255

crate enclosure form-factor. In addition to the custom 205 electronics that reside in these crates, there must also be a single "controller" for each crate. Considering all four experimental halls, this exceeds 150 controllers.

There are many commercial off-the-shelf options for this type of controller, and our general requirements do 210 not extend beyond what is currently commercially available. We do have some specific requirements that narrowed the viable choices.

We purchased VME controllers from several vendors

for development purposes and made a significant invest-215 ment in custom software that runs on all of the existing boards. We also benchmarked our code and have come 260 to expect certain "minimum" requirements for performance from the chosen architecture within a specified Linux operating system. 220

We also expect a certain minimum 10-year time frame in which these controllers will be supported by <sup>265</sup> the vendor with respect to the available parts, repair, and software updates. Our VME controller requirements are summarized as:

225

240

- Single-slot VME form factor no required rear transition module;
- Intel Core i7 dual- or quad-core embedded processor 2 GHz (or greater);
- Hyperthreading and 64-bit arch support; 230
  - 4 GByte DDR3 (1066 MHz) ECC SDRAM (or greater);
  - Front-panel gigabit Ethernet and serial port console;
- 1 x4 PCI Express XMC expansion slot (or greater); 235
  - VME320-interface using the Tundra Tsi148 chip;
  - Support for all VME transfer modes including 2eSST;
  - VXS optional: interface supporting both VITA 41.3 (Gig E) and 41.4 (PCIe) standards.

After several different boards were evaluated, we purchased VX915 Intel 4th Generation quad-core i7-based VME single-board computers from Concurrent Technologies, and some number of the XVR16 Intel i7-based VME single-board computers from GE. They were installed in the 69 crates for CLAS12 and have demonstrated excellent performance and reliability. Most of the controllers send data over their built-in 1 Gb link, while for a few of them, a 10 Gb XMC daughter board was installed to increase the output bandwidth. The maximum data rate from a single crate in CLAS12 never exceeds 130 MB/s, and with that rate the quad-core controllers are able to handle the VME data polling, event processing, and sending over the network to the EB without any issues.

### 4.5. Trigger Distribution System Modules (TS, TD, TI)

The TCS (TRIGGER, CLOCK, SYNC, and BUSY) distribution system [5] is the hardware interface to bridge the Trigger and DAQ systems. The TCS system receives the trigger decision from the Trigger system, and initiates data readout for the DAQ system by distributing the readout trigger (TRIGGER) signal. Additionally, it distributes a 250 MHz system clock (CLOCK) to pipeline the system, and it distributes an encoded synchronous signal (SYNC) for the system synchronization. It monitors the front-end electronics status (BUSY) and makes sure of the smooth data readout of the experiments. Figure 3 shows a diagram of the trigger and TCS distributions.

Figure 3: Diagram of the trigger and TCS distribution.s The VTP boards generate triggers using detector signals from the front-end crates. The final trigger decisions, up to 32 trigger types, are sent from the VTP to the TS for data readout. The TS distributes the TCS to the TD through the SD and the backplane, then to the front-end crates through optic fibers and the TI. The TI collects the front-end board busy signals and sends them to the TD, which throttles (disables) the readout trigger distribution on the TS.

The main hardware components of the TCS distribution system include a Trigger Supervisor (TS) board [6] (see Figs. 4 and 5), Signal Distribution (SD) boards [7], Trigger Distribution (TD) boards [8] (see Fig. 6), Trigger Interface (TI) boards [8]) (see Figs. 7 and 8), VXS

4

- crates, and optical fibers. The TS board, one SD board, 275 and up to sixteen TD boards are located in the global TCS distribution VXS crate. One TI board and one SD board and/or one FANIO board are located in each front-end crate. The electronics boards were custom de-
- signed and produced for the 12 GeV upgrade. Field Pro-280 grammable Gate Arrays (FPGAs) are used for TCS generation, control, and decoding. Optical fibers are used to transmit signals at high speed over long distances and the high-speed serial backplane for internal crate distribution.

285

Figure 4: Trigger Supervisor (TS) board. The TS board is a 6U by 160 mm VME board with VXS connector. It generates and distributes 310 the readout triggers, synchronization signals, and clock (either from the front-panel input or the on-board oscillator) to the TD boards via the SD through the VXS backplane.

#### 4.5.1. Clock Distribution

290

The TCS system uses the 250 MHz clock that comes from the TS in the global trigger distribution crate. This clock is either generated by the TS on-board oscillator or its front-panel input. The clock is fanned out 320 to the VXS P0 connector and then to the SD board. The SD fans out the clock to the TD boards via the VXS P0 backplane. The TD boards further fan out to the TI boards via optic fibers. The TI uses this clock to generate clocks with proper frequencies (250 MHz, 325 295 125 MHz, 62.5 MHz, 31.25 MHz, and 41.67 MHz) and

- sends the clocks to the front-end crate SD board, and the SD fans out to the front-end DAQ modules (TDCs, ADCs). The fan-out buffer level is minimized on every board to limit the clock jitter. The slower clocks derived 330
- 300 from the main system clock are phase aligned thanks to the Analog Devices AD9510 with a synchronous phase re-alignment command. The clock jitter is about one

#### TS board block diagram

Figure 5: TS board diagram. The TS generates the readout triggers from up to 32 front-panel trigger inputs and up to 32 backplane trigger inputs (from the GTP), and sends out the triggers via encoded 16-bit words to the backplane.

picosecond measured at the front-end electronics. The clock distribution skew can be adjusted by the SD clock delay if necessary.

#### 4.5.2. SYNC Distribution

The TS generates and distributes the SYNC signal. The SYNC is an encoded 4-bit serialized command transferred at 250 Mbps synchronized with the system clock. Normally, the serial SYNC line stays at logic high (or '1'). When transferring a SYNC command, the SYNC goes to logic low for one bit, followed by the 4bit command code. After the 4-bit SYNC command, the SYNC goes to logic high again. There is a minimum of four '1's before the next cycle begins. The SYNC start is phase aligned to the 62.5 MHz clock used for the trigger word transfer, the 41.67 MHz clock used for the CAEN TDC boards, and the 31.25 MHz clock used for Flash ADC boards. This phase relation is used to synchronize the slower clocks on the TI to the 62.5 MHz clock on the TS. This also limits the SYNC command to no more than one per 96 ns. To facilitate the ACcoupled optical transceivers, the SYNC is Manchester encoded on the TS and the TD, and Manchester decoded on the TI and the TD.

The SYNC is phase aligned with the 250 MHz system clock on the TI boards using their FPGA's IODELAY. The SYNC is synchronized across the TI boards by applying different delays on the individual TI boards. The delays are determined by the fiber latency measurement.

The spare fibers between the TD and TI boards are used to measure the fiber latency. The TI sends a test

Figure 6: Trigger Distribution (TD) board. The TD board is a 6U by 160 mm VME board with VXS connector. It receives the TCS from the TS via the VXS backplane, and distributes the TCS via the front-panel QSFP optic links. It collects the BUSY inputs from up to eight TI boards, and generates the readout buffer busies for up to eight front-end crates. The TD sends the collective BUSY to the TS to back pressure the trigger generation.

signal to the TD through one fiber, and the TD loops back the signal through another fiber. The TI measures the delay between the test pulse and the looped-back test pulse using the FPGA counter and the carry chain in the FPGA. As the fiber skew is small (less than 1 ns for 100 m fibers), the measurement on these two fibers

can be used as the latency of the other fibers in the cable. After the SYNC latency compensation, all of the TI boards receive the SYNC at the same time with the skew of one system clock period, which is 4 ns. The synchronized SYNC signals are used to synchronize the triggers
 as described next.

#### 4.5.3. Trigger Distribution

The trigger words, which include the readout trigger signals and event information (event type, trigger timing, etc.), are generated and serialized on the TS. The serialized trigger word is fanned out by the SD board

serialized trigger word is fanned out by the SD board and the TD board, and deserialized by the TI board. The 370
 16-bit trigger words are summarized in Table 1.

Both the fiber latency and trigger word serializer/ deserializer are compensated so that all of the TI boards send the readout trigger at the same time to the frontend data acquisition electronics. The SYNC is used in conjunction with a synchronous FIFO to enforce a fixed latency on the trigger distribution. Figure 9 shows the diagram of the compensated trigger distribution.

360 On the TI board, the deserialized trigger word is

Figure 7: Trigger Interface (TI) board. The TI board is a 6U by 160 mm VME board with (or without) the VXS connector. It uses the same printed circuit board (PCB) as the TD board with modified component population. It receives the TCS from the TS/TD or a subsystem controller via fiber, and collects the BUSY and sends it to the TS/TD via the same fiber. The TI can also be used as a subsystem controller in the so-called master mode.

Bit 15:12	Bit 11:10	Bit 9-0	Comment
1001	Quadrant timing	Event type	GTP major trigger
1010	Quadrant timing	Event type	Ext major trigger
1011	Four TS partitions	' event types	TS partitioning (4, 3, 2, 1)
0110	Quadrant timing	Trigger source Event type	TImaster legacy Trigger (TS) VME trigger
0101	Trigger command/Control	VME command	
0100	TS timer (TS time bit(13:2))	TI Sync check	
0111	Trigger content	Additional trigger info	

Table 1: Trigger word definition. The TS encodes the readout trigger, event type, and the fine timing (4 ns quadrant) information into a 16bit word, which is transferred every 16 ns. This 16-bit word can also be some system setting information or the system timer when there is no readout trigger in the 16 ns period.

clocked into and clocked out of a FIFO using the 62.5 MHz clock. At the start-up, the FIFO is reset (0 words) and the FIFO read/write is disabled. The serial trigger link is idle words only. On trigger start, the TS starts trigger word transmission. The TI will write the deserialized data (valid data, that is a non-idle data word) to the FIFO. After some pre-set delay (VME register controlled), the TS issues a 'Trigger Start' command on the SYNC link. When TI receives the 'Trigger Start', the TI resets the trigger FIFO readout address, and enables continuous readout of the FIFO. As the SYNC lines are fiber length adjusted and the 62.5 MHz clocks are phase aligned, the trigger words from the TI board FIFO are synchronized across the system. The trigger word also has the fine trigger timing information. By decoding that, the TI board distributes the trigger in 4 ns precision, although the trigger word is serialized every 16 ns. If the system clock phase is not adjusted, there will be a maximum of 4 ns skew among the clocks

Figure 8: TI and TD board diagram. The TI and TD use the same PCB design, but different component population and FPGA firmware.

on the TI boards, and the same is true for the readout 410 trigger. The clock phase can be adjusted by the SD if the skew is critical to the system.

# 4.5.4. DAQ Synchronization (Trigger Throttling) Control

- Because of the finite memory size and the randomness of the triggers, it is possible for the memory to become overwhelmed somewhere in the system, which could cause DAQ problems. The TCS throttling mechanism is used to prevent possible memory overflows,
- and to keep the DAQ synchronized. Figure 10 shows the DAQ synchronization logic implementation. Three methods are used to keep the DAQ synchronized. These include trigger rules and event limit setting, pipeline DAQ, and synchronization events (special events).

### 395 4.6. Signal Distribution Module (SD)

The Signal Distribution (SD) board [7]) (see Fig. 11) occupies the "B" switch card slot as specified in VITA 41. The main purpose of this module is to distribute the signals received from payload slot 18 (Trigger Inter-

face board) of a VXS crate to the 16 other payload slots
 occupied by FADC, DCRB, VSCM, or any other VXS
 front-end boards.

The SD module distributes the 4 LVPECL differential pair signals from payload slot 18 to the 16 VXS pay-

405 load slots within the crate. This is done using the highspeed, point-to-point connections from the switch slot to each payload slot. The four distributed signals are length-matched to minimize the output jitter seen on all of the payload slots. Three of the four remaining pairs

Figure 9: Trigger synchronization between TIs. The TI boards delay the decoding of the received readout trigger by the complement of the TS/TD to TI transfer latency, so that all front-end boards receive the readout trigger simultaneously.

are LVDS signals routed from the each payload module to the FPGA on the SD module. The last pair is an LVDS signal routed from the FPGA on the SD module to each payload module. Each of the 16 payload modules has a single-ended signal to the SD module and one from the SD module back to the payload module.

# 4.7. Flash ADC Module (FADC250)

A 16-channel, 250 MHz pipelined flash ADC (FADC) [9] (see Fig. 12) with 12-bit precision was designed to digitize and process the detector pulses for experiments at JLab. The FADC250 module (see diagram in Fig. 13) conforms to the VITA 41 VME64x switched serial (VXS) standard. Each channel of the module accepts input signals on a LEMO style coaxial connector and has three user-selectable ranges (0.5 V, 1.0 V, 2.0 V). Differential signal conditioning scales the input signals to within the dynamic range of the ADC and a single-pole low-pass filter limits the signal bandwidth to the Nyquist band of the converter (125 MHz). Individual channel offsets are accomplished by means of DACs under VME control. Each channel has its own dedicated ADC chip (Analog Devices AD9230). Both positive and negative polarity input signals are supported. The 250 MHz clock is distributed to the ADC chips through a low jitter (<2 ps) network.

Digitized data from the 16 FADC chips is processed and formatted for readout in a pair of high performance Xilinx FPGAs. The digitized data from the ADCs follows two distinct paths. Logic in the trigger data path pre-processes data for the trigger algorithms of the VXS

415

Figure 10: DAQ synchronization logic. Three methods are used to keep the DAQ synchronized: trigger rules and event limit setting, pipeline DAQ, and synchronization events.

<sup>440</sup> Trigger Processor (VTP). The FADC250 module continuously streams this data to the crate VTP located in VXS switch slot A via high-speed serial links of the VXS fabric. Data from multiple VTPs and other modules are used to form a global trigger signal that is returned to the crates to initiate data readout.

The readout data path continuously stores digitized data for each channel in circular buffers. When a trigger signal is received by the module, a programmable window up to 2  $\mu$ s wide of digitized data is extracted

- <sup>450</sup> from the buffers for processing. The starting point of this window can be programmed up to 8  $\mu$ s earlier than the arrival of the trigger signal to account for the time required to form the trigger signal. Zero suppression on the extracted data may be implemented for each channel
- using programmable thresholds. A lossless data compression algorithm can also be applied to the data of each channel with typical compression factors of 2 to 3. The design is pipelined so that data from multiple triggers can be processed simultaneously. Triggers sep-
- 460 arated in time by as little as 50 ns can be accepted by the module. The trigger number and trigger time (clock periods since last synchronization) are reported along with the channel data so that data from multiple modules can be correctly assembled into events.
- Data associated with a programmable number "N" of triggers is packaged into a block of data for readout over VME. "N" can take values from 1 to 255, with 40 being a typical value chosen. Data is stored in an on-board 490 8 MB SRAM as 64-bit words to match the 64-bit high-
- <sup>470</sup> speed (200 MB/s) dual edge VME Source Synchronous Transfer (2eSST) mode employed to read out the mod-

Figure 11: Signal Distribution (SD) board. It distribute the signals received from payload slot 18 (Trigger Interface board) of a VXS crate to the 16 payload slots.

ule.

In order to save the overhead of setting up a DMA transfer for each FADC250 module in the crate, a chained block readout mechanism with token passing is used. A common address range is enabled for all modules in the crate but only the module having the token will respond to a read request. A single logical DMA read is initiated by the VME crate controller and the first module in the chain supplies data from its block of event fragments. When the block data from the first module is exhausted, a token signal is passed to the next module in the chain and this module then proceeds to transmit its data from its block. When the block for the data from that module is exhausted, it transfers the token to the next module. This continues until the data from the last module in the chain is exhausted. Instead of passing the token, the last module asserts the VME bus error signal (BERR), which terminates the DMA cycle. The user returns the token to the first module and the process can begin again when the next block of events is ready for readout. The user does not have to query the modules in advance to discover the number of words to read out.

Figure 12: Flash ADC module (FADC250). The 16-channel, 12-bit, 250 MHz digitizer in VXS format is capable of providing information to both the readout chain over the VME bus and the trigger logic over the VXS serial lines.

Figure 13: Flash ADC module diagram (FADC250). In addition to <sup>510</sup> pulses readout and trigger information, it is equipped with scalers for every input channel.

The DMA is set up with a total number of words larger than any expected value for the entire crate. Data from <sup>515</sup> each module is tagged with the slot number to identify its source. The token passes along a VXS signal line to VXS switch slot B, where a module there (SD) routes it to the next enabled module.

### 500 4.8. Discriminator Scaler Module (DSC2)

505

The JLab Discriminator Scaler Module (DSC2 [10], see Fig. 14) is a 16-channel general-purpose discriminator and scaler module designed as a 6U VME card. It replaces an older design, improving on jitter, noise, <sup>525</sup> cross-talk, and adding new features. The board specifications are summarized in Table 2.

Figure 14: Discriminator Scaler module (DSC2). 16-channel generalpurpose discriminator and scaler module designed as a 6U VME card.

Property	Value		
Analog Discriminator			
Threshold	0 to -1023 mV		
Pulse width	4 ns to 40 ns		
Dead-time	4 ns typ. w/8 ns pulser width		
Maximum input rate	>125 MHz		
Ch-ch isolation	>65 dB		
Threshold noise	1.3 mV RMS (typical)		
Slew-rate delay dispersion	<20 ps		
Input-to-output delay	<5 ns		
Digital Processing			
Digital delay step	4 ns		
Digital delay maximum	1 μs		
Digital width maximum	1 μs		
Maximum count rate	125 MHz		

Table 2: DSC2 discriminator board specifications.

Typically one threshold is used for time-to-digital applications and the other threshold is used for trigger applications. There are separate differential ECL outputs for each channel and threshold. Low jitter performance was an important goal of the design as this module will be used in high resolution applications. Figure 15 shows the typical jitter as a function of a variety of input slew rate signals and threshold overdrive conditions.

Digital Processing. A Xilinx Spartan 3A FPGA is used to implement the VME interface, scalers, discriminator controls, and scaler event building features. Each channel and threshold has two scalers associated with it. The first scaler counts all threshold crossings for the input. The second scaler is gated using a front-panel input source, which can be useful to compute the dead-time of channels and many other applications. Additionally, reference scalers are accumulated (a gated and ungated version) that count the elapsed time, which can be used to normalize inputs scalers to Hz. All together there are 68 scalers, which can be slow to read over VME if using single-cycle transfers. An event builder is implemented that can synchronously read (and optionally

Figure 15: Output jitter vs. input slew rate and overdrive for the DSC2.

clear) all scalers and build an event with this data. Over 100 events can be buffered and readout using the VME 2eSST protocol at 200 MB/s.

### 4.9. TDC Modules (v1190/v1290)

- <sup>535</sup> Commercial CAEN V1190/V1290/V1290N TDC [11] boards (see Fig. 16) are used for timing measurements in the PMT-based CLAS12 detectors. The V1190 has a timing resolution about 100 ps and the V1290 about 35 ps.
- All boards installed in CLAS12 run on an external 250/6=41.666 MHz clock rather than the internal 40 MHz clock. The use of a different clock required compensation table remeasuring and reloading. That table is implemented to compensate for the integral non-
- 545 linearity (INL). The INL of the TDCs represents the binby-bin accumulated error of the input-output characteristic of the TDC with respect to the ideal response.

The compensation tables for the CAEN V1190A and VX1290A TDCs are stored as tables in the unit SRAM

- <sup>550</sup> memory. Initial tables are measured at the factory and come preloaded on the modules. These tables are reasonably accurate when operating the module using its internal 40 MHz/25 ns period clock. However, in CLAS12, the modules are strobed with an external
- <sup>555</sup> clock of a slightly larger frequency of 41.67 MHz. This difference in the frequency has a non-negligible affect on the INL tables. For our purposes we use a high-<sup>570</sup> frequency pulser to populate the full dynamic range of the TDC within the CLAS12 readout clock. The mea-
- <sup>560</sup> sured INL tables that were derived from this calibration were written into the TDC memory to replace the factory-loaded values. Details on the procedure and the residual non-linearity affects are given in Ref. [12].

Figure 16: CAEN V1190 TDC module (V1190). The 128-channel, 100 ps LSB TDC board in VME format is shown. Another board in use is the V1290 with 32 channels and 25 ps LSB.

# 4.10. Drift Chamber Readout Board (DCRB)

Figure 17: Drift Chamber Readout Board (DCRB). 96-channel amplifier, discriminator, and time-to-digital converter module in VXS format.

The Drift Chamber Readout Board (DCRB) [13] (see Fig. 17) is a 96-channel amplifier, discriminator, and time-to-digital converter module used to digitize and readout hits from the CLAS12 drift chambers [14]. A single VXS crate of DCRB modules can readout a full region of the drift chambers for a single sector of the CLAS12 Forward Detector, resulting in 18 VXS crates of DCRBs to instrument the full 6 sectors each having 3 regions of drift chambers.

Analog Inputs. Each DCRB receives 96 differential analog signal pairs using twisted-pair cabling from the

drift chamber pre-amplifiers. The pre-amplifiers lo- 625 cated on the detector provide a gain of 2.3 mV/ $\mu$ A. On the DCRB each analog input channel is amplified by a voltage gain of 30 and then discriminated by a programmable threshold (common to all channels on the

580

585

board with an effective chamber readout threshold range of 0 to  $3.5/\mu$ A for each sense wire signal).

TDC Event Builder. All discriminated channels go to a Xilinx Spartan 6 FPGA where a 96-channel, 1 ns resolution time-to-digital converter (TDC) is implemented in firmware. The TDC is based on the ISERDES2 shift

- register FPGA primitive that directly samples the digital input with a single-data-rate (SDR) input register clocked at 1 GHz. The TDC sampling clock is synchronized to the CLAS12 master oscillator, making it 590 easy to relate hit times in the drift chamber to the other detectors in CLAS12. The TDC inputs are buffered to support multiple hits, allowing for an average hit rate
- of 4 MHz per input before loss of data, which exceeds 630 the chamber design hits rates by a few orders of magni-595 tude. Hits from groups of 16 channels are written into a large buffer that a linked-list content addressable memory (CAM) tracks for 16  $\mu$ s. When a L1A trigger signal is received, a time window of hits is extracted from the
- TDC hit buffer. The readout window times are supplied 600 to the CAM, and the CAM provides the address of the last hit matching each readout time bin. The hit buffer  $_{\scriptscriptstyle 635}$ is then read to extract the hit and also the address of the next hit in the buffer matching the time bin (this is
- the linked-list behavior). The result is an extremely fast 605 event builder with natural zero suppression that does not require time-sorted data. Cleanup is accomplished by a timer that invalidates the CAM entries after time bins are older than 16  $\mu$ s. Hits for an event are assembled 640
- and buffered in a 2 MByte external RAM, which is read-610 out through the VME bus using the 2eSST protocol at 200 MB/s.

*Calibration Support.* A programmable amplitude pulse generator is implemented that can inject test pulses directly into the DCRB differential amplifier inputs, as 615 well as to the pre-amplifiers that are on the detector. This provides a way to test points of failure, check channel gain, and check channel delays without any extra equipment. A scaler is implemented on each channel for slow controls monitoring of all chamber wires.

### 4.11. VXS Silicon Readout Module (VSCM)

The CLAS12 Silicon Vertex Tracker (SVT) [15]) 655 front-end utilizes the data-driven FSSR2 ASIC for digitization. The VXS Silicon Readout Module

(VSCM) [16] (see Fig. 18) was designed to interface the FSSR2-based front-end to the CLAS12 DAQ system. This system is capable of reading out all 33,792 SVT channels in 3 VXS crates.

Figure 18: VXS Silicon Readout Module (VSCM). Designed to interface the FSSR2-based Silicon Vertex Tracker detector front-end to the CLAS12 DAQ system.

The main features of the VSCM include:

- Receives 8 FSSR2 streams, each at 840 Mbps;
- De-randomizes hits into an 8  $\mu$ s buffer;
- 512k hit, multi-event buffer;
- Supports >1 MHz trigger rate;
- Programmable amplitude charge injector;
- 1 ns resolution time-to-digital converter (TDC);
- Per-channel hit scaler;
- FSSR2 synchronization, status, and control.

Event Builder. The VSCM deserializes the FSSR2 streams, checks for errors, and decodes the hits, which are stored in an 8  $\mu$ s circular memory. The hits are not guaranteed to be time ordered, so the time stamp and channel number are used to form the circular memory address (rather than storing in the order received). The VSCM also implements an 8-channel, 1 ns time-todigital converter (TDC) that measures the logic OR of the hits from each FSSR2 ASIC. This high time resolution is significantly better than the FSSR2 serial stream hit time resolution and is required for improved out-oftime hit rejection. The L1A trigger signal time is used to look back a fixed amount of time and extract a time window of hits from the circular memory, which corresponds to the physics event. Non-zero hits are assembled as an event and buffered in a 2 MByte external RAM that is readout through the VME bus using the 2eSST protocol at 200 MB/s.

The event data contains primarily two hit word types that together provide high time resolution and spatial hit

Property	Description
Hit Time	128 ns resolution
Channel	0-1023 strip ID
Charge	0-7 threshold

Table 3: VSCM data: low time resolution hit word

Property	Description	
Hit Time	1 ns resolution	
Channel	0-7 chip ID	

Table 4: VSCM data: high time resolution hit word

resolution while keeping the front-end complexity low (see Tables 3 and 4).

Figure 19 shows the hardware block diagram of the module. Essentially, a single low-cost Xilinx Spartan 6 FPGA was used to implement the deserialization, buffering, event-building, monitoring, front-end configuration, time-to-digital conversion, and monitoring.

660

670

Figure 19: VSCM Hardware Diagram. Low-cost Xilinx Spartan 6 FPGA was used to implement board logic.

### 665 4.12. SSP Board as Fiber Readout Module

The SubSystem Processor (SSP) [17]) was originally designed to work as part of CLAS12 Trigger System, <sup>705</sup> but the optical transceivers, FPGA, and DDR2 memory are also suitable for remote front-end synchronization and readout. The SSP resides in a standard VXS crate configuration and acts as a bridge between custom frontend electronics (up to 32 remote front-ends per SSP) <sup>710</sup>

and the VME based CODA readout components. It collects event data from up to 32 fiber optic links, buffers events in the 4 GByte DDR2 memory, and is read out by the crate controller using the 2eSST VME protocol at up to to 200 MB/s. The CLAS12 Ring Imaging Cherenkov Counter (RICH) [18], Micromegas Vertex Tracker (MVT) [19], and Forward Tagger Tracker (FT-Trk) [20] subsystems utilize the SSP in fiber readout mode. The board description can be found in Ref. [2].

### 4.12.1. Readout of the Micromegas Trackers

680

685

690

The MVT is a part of the CLAS12 Central Detector [19]. The 6 layers of the curved barrel detectors and the 6 forward discs account for about ~18000 and ~6000 readout channels, respectively. Two doublesided Micromegas discs form the FT-Trk tracker with some 4000 channels, which is a part of the CLAS12 Forward Tagger [20]. Under the harsh operating environment of the MVT and FT-Trk (stringent space limitations, imposed low material budget, high radiation environment, up to 5 T magnetic field), it was decided to implement readout systems with off-detector front-ends. Micro-coaxial cables of low 40 pF/m linear capacitance transfer non-amplified signals from the detectors to the front-end units (FEU) placed 1-2 m away. Figure 20 shows the MVT/FT-Trk block diagram.

Figure 20: MVT/FT-Trk Readout System. Both the front-end and back-end are shown.

The FEUs (see Fig. 21) are equipped with the DREAM ASIC, specially designed for the CLAS12 application [21]. Each of the 64-channels of the DREAM chip includes a charge-sensitive amplifier adapted to a wide range of detector capacitances (up to 1 nF), a shaper with a wide range of programmable peaking times (75 ns to 1  $\mu$ s), and a 512-cell deep Switched Capacitor Array (SCA) used as the trigger pipeline memory and de-randomization buffer. The input signals are continuously sampled and stored in the SCA. Upon reception of the trigger signal, a programmable number of samples of all channels is fetched from the memory locations corresponding in time to the event and is

read out serially. The sampling is not stopped during <sup>745</sup> the readout process, allowing nearly dead-timeless operation. With the 25 MHz sampling and readout frequencies, and with 6 to 8 samples retained per event, the DREAM channel memory is enough to tolerate the

715

targeted 20 kHz event rate with 8 μs trigger latency. 750
The 512-channel mixed analog-digital FEU includes
8 DREAM ASICs, an 8-channel serial AD9222 ADC
from Analog Devices, a Virtex-6 Xilinx FPGA, opti-

- <sup>720</sup> cal and electrical SFP modules, and several other services and monitoring circuits. The FEU is responsible <sup>755</sup> for the configuration and the readout of the DREAMs, for analog-to-digital conversion of the signals, for the pedestal equalization, coherent noise subtraction, and
- <sup>725</sup> zero suppression. The event fragments are then formed from the data of the retained channels and transmitted to the back-end electronics over a 2.5 Gbit/s optical link. Each FEU consumes about 20 W. The 48 MVT FEUs and the 6 FT-Trk FEUs are housed in ad-hoc crates.
- <sup>730</sup> Continuously flowing air ensures an ambient temperature of 35°C within the crates. The MVT front-end electronics operate in up to a 1 T residual magnetic field of the solenoid.

Figure 21: The 512-channel front-end unit (FEU) for the CLAS12  $\,^{760}$  MVT and FT-Trk readout.

735

The back-end electronics are based on the standard VXS crates including the crate controller SBC, TI and SD modules, and the SSP boards described in the previous sections. Dedicated SSP firmware has been developed to implement synchronous distribution of the system clock, trigger, and control signals from the SSPs

to the FEUs over the 2.5 Gbit/s optical links. For each trigger, the SSPs perform local event building tasks as sembling FEU event fragments. Multi-event buffers are formed and transferred from SSPs to the crate controller SBC over the VME64 backplane using the 2SST proto-

col. Transmission rates of 200 Mbyte/s are routinely achieved. A single SSP can communicate with up to 24 front-end units.

The SBC runs the Readout Controller (ROC) application of the CLAS12 CODA data acquisition framework [22]. It completes the data integrity checks performed in the SSP firmware, disentangles multi-event buffers, forms MVT and FT-Trk events, and sends them to the event builder over a 10 GB/s Ethernet link. The MVT and FT-Trk readout electronics are continuously surveyed by the CLAS12 detector monitoring system using the EPICS framework [23].

# 4.12.2. Readout of the Ring-Imaging Cherenkov Detector

Figure 22: RICH front-end tile (128 channel version).

The CLAS12 Ring-Imaging Cherenkov Detector (RICH) [18]) contains 391 multi-anode PMTs (MaPMTs), corresponding to 25024 channels of readout. The front-end electronics are equipped on-detector, forming compact modules called "tiles" (see Fig. 22) that are comprised of the MaPMT, adapter, ASIC, and FPGA boards. There are 138 tiles needed to readout a single sector of the detector (currently there is only a single sector installed). Each tile contains either 128 or 192 channels and uses the MAROC3A ASIC for gain equalization, shaping, and discrimination of the MaPMT pulses. Each tile also has an FPGA board that performs a 1 ns time-to-digital conversion measurement for leading and trailing edges of the amplified and discriminated MaPMT pulses.

All 138 tiles are distributed across 5 SSPs located in 805 a single VXS crate using ~20 m 2.5 Gbps optical links. 775 The tile FPGA buffers the TDC hits in on-chip memory waiting up to  $\sim 8 \ \mu s$  for a fixed latency trigger. Given the low hit occupancy of events, the RICH DAO can accept trigger rates close to 100 kHz before contributing to 810

significant deadtime. The data rate for the single RICH 780 sector is typically under 10 MB/s for CLAS12 trigger rates around 15 kHz.

# 5. Software

### 5.1. CODA DAQ Software

- The CLAS12 DAQ system is based on the CEBAF 785 Online Data Acquisition (CODA) system ([22] developed at JLab (see Fig. 23). CODA is a software toolkit of applications and libraries that allows the implementation of a data acquisition system. The scale of the system can range from a few detector channels in a test
- stand to tens of thousands of channels in a large detector installation in one of the experimental halls. CODA achieves this scaling through modularity and provides a set of supported hardware components along with complementary software components. 795

Figure 23: CODA System Diagram. Every box represents a multithreaded program running on a corresponding controller or server. All communication between programs is done over Ethernet using TCP/IP protocol.

#### 5.2. Run Control

800

The CODA DAQ system includes a Run Control facility consisting of a back-end Run Control supervisor and a front-end graphical operator display that connects to the supervisor and controls its operation. The supervisor in turn controls operation of the many CODA components that participate in the DAQ configuration. The latter are defined in run configuration files that the operator chooses at startup. The Run Control GUI (see

Fig. 24) presents the operator with a choice of possible actions that depend on the current state of the run. The supervisor translates the operator's choices into appropriate commands to the individual components. Alternatively, limited communication with the supervisor can be performed via command-line scripts. In addition, the supervisor monitors the health and operation of the CODA components and warns the operator or pauses the run if problems are detected.

Figure 24: Run Control GUI. Main control and monitoring screen for the CLAS12 DAQ system. The tabs along the top on the right side allow for switching between different control screens, such as the configuration editor, current DAQ component statuses, and DAQ rates

#### 5.3. Front-End Libraries

The front-end libraries for the DAQ system were mostly developed at JLab. These include: GEFANUC driver:

- Customized kernel driver and user space interface
- C API provides:
  - Setup of VME inbound and outbound windows
    - \* Permanent windows: CRCSR, A16, A24, A32
    - \* Map of these windows into user space
  - Allocate Physical Memory for DMA
    - \* Map of this memory into user space

JVME User space Driver:

- C API provides
  - common user space interface to GEFANUC driver and others
  - Initialization of kernel driver and default VME windows

- Maps VME bridge registers into user space
  - \* Provides userspace configuration and operation of DMA

005

 Initialization of and access to shared memory mutex for intra-process cooperation during DMA

Front-end Libraries:

- C APIs provide
  - thread safe
  - module register mapping in VME windows to memory structures.
  - configures modules for readout via
    - programmed i/o
      - \* Single module DMA
      - \* Multiple module DMA
        - Token passing (P0/VXS and CBLT) with common A32 address range
        - Linked List DMA

### 5.4. Readout Controller

The Readout Controller (ROC) (see Fig. 25) software component is a C program running on the front-end controllers such as the Intel-based VME/VXS crate con-

- trollers, VTP trigger boards, or regular Linux servers essentially any hardware receiving data from the frontend electronics. On DAQ startup, the ROC main program starts three threads. After this it just controls the thread health and communicates with the Run Control
- <sup>860</sup> process. Three threads (readout, processing, and network) pass data from one to another, communicating via circular buffers. The typical number of buffers in each buffer queue is 8 and the size of every buffer is 4 MB, <sup>895</sup> which defines how long the front-end electronics can be read out before blocking triggers in the assa of healt and
- read out before blocking triggers in the case of back-end busy conditions.

The first thread (readout) receives data from the frontend electronics and places it into the first circular buffer. 900 That thread can run in polling mode, which occupies

- an entire CPU core (or optionally in interrupt mode).
   The CLAS12 readout primarily employs polling mode, which has adequate performance on multi-core controllers. The second thread (processing) reads data from 905 the first circular buffer and performs all needed data pro-
- erssing. In particular it performs the so-called "disentangling", as well as data sanity checks. The results are placed into the second circular buffer. The processing component can create its own worker threads to increase processing power if necessary. The final thread

(network) reads data from the second circular buffer and sends it over the network to the Event Builder.

The first and second threads can load user code that is compiled separately and downloaded dynamically at runtime, which allows users to develop experimentdependent processing without recompiling the entire ROC application.

Figure 25: Readout Controller (ROC) Diagram. The ROC program typically runs on a 4-core VME Intel Controller. It includes 3 main threads performing VME readout, data processing, and networking.

# 5.5. Event Builder

The Event Builder (EB) (see Fig. 26) is the program that receives the data fragments from all readout controllers and assembles it into events. The building process is based on event number, event type, and time stamp of the data fragments: for each event, all three values have to be identical for all data from all Readout Controllers. In case of any differences, the DAQ will be stopped and the error reported.

The Event Builder consists of receiving and building parts. The receiving part contains a set of independent threads, one per Readout Controller connected to it by TCP protocol. Every thread receives data and places it into an internal buffer. If the buffer becomes full, the thread stops receiving data, effectively propagating the busy condition back to the Readout Controller. The building part has a number of identical building threads, which take turns by getting data from the receiving part of the internal buffers, building events, and placing them into Event Transfer System.

The total number of threads in the receiving part of the Event Builder in the CLAS12 DAQ is currently 118, which therefore represents the number of network connections from the Readout Controllers. Because of this the DAQ has to run on a powerful server, with many

835

845

CPU cores, large memory, and a high bandwidth network card. CLAS12 is using a Dell R730 server with 32 cores, 64 GByte memory, and 40 Gbit network card. This server is adequate for the present CLAS12 DAQ

Figure 26: Event Builder (EB) Diagram. The EB program typically runs on a multi-core Linux server. It collects event fragments from the ROCs, builds events, and sends events to the Event Transfer system.

Build Thread N

### 5.6. Event Transfer

915

ROC117

ROC118

920

The Event Transfer (ET) system (see Fig. 27) provides the user with an efficient method for moving bulk data between processes. The ET was not designed as a messaging system but a shared memory system that can<sup>955</sup> be visualized as data containers moving around a circular railway track. In this metaphor, a producer of data (the Event Builder) requests an empty container, fills it

- with data, tags it with metadata describing the contents, and places it at the start of the track. Stations along the
   track are assigned algorithms for testing the metadata and selecting the containers of interest. The user has the option of making a station blocking or non-blocking. A
- container stopped at a blocking station holds up all of the other containers behind it on the track. A data consumer attached to the station processes the data in the container and has the option of either putting the container back on the track, where it proceeds to the next
- station, or returning the container to the station at the start of the track, effectively discarding the data. In the simple example diagram shown in Fig. 27, a data monitoring consumer attaches to a non-blocking station that samples the data of interest. The Event Recorder at-
- 940 taches to a blocking station and records the content of every container to disk. The container is then returned to the start of the track.

Using these simple concepts, complicated data path- 975 ways can be constructed. The ET package supports

945 remote consumers connecting to stations over the network, allowing load sharing between multiple machines.

Figure 27: Event Transfer (ET) System Diagram. The ET program typically runs on a multi-core Linux server. It accepts events from the Event Builder and passes them through the set of stations, allowing attached programs to perform data processing. The last station typically has the Event Recorder attached to it.

### 5.7. Event Recorder

950

The Event Recorder (ER) (see Fig. 28) is the software component that receives data from the ET system and records the data in files onto a disk. The ER can write data to one or several files in parallel (so-called multi-stream mode). If multi-stream mode is used, the event order is preserved, but it requires the ER allocated memory size to be larger than the number of streams multiplied by the individual file size.

The ER structure in multi-stream mode is shown in Fig. 28. The distribution thread receives data from the Event Transfer system, searches for the free writing thread, and grabs its semaphore. It starts filling up the buffer of the thread with data until it becomes full. After that it signals the writing thread to start writing the entire buffer to the specified output file name. The writing thread marks itself "busy" and writes data to the file, and after that, it becomes "free" again. While the writing process is in progress, the distribution thread grabs another free writing thread and the process repeats. The writing performance of the ER can be increased by increasing the number of writing threads.

#### 5.8. Messaging System (ActiveMQ)

The messaging system in the CLAS12 DAQ system is based on the ActiveMQ library and its C++ extension. Two ActiveMQ servers are used to route all communications. The number of connections to ActiveMQ is several hundred, and the number of messages sent every second is several tens of thousands, with data volumes of a few tens of MBytes per second. The messaging system is used in particular to monitor and control the DAQ components, in addition to the Run Control process.

Figure 28: Event Recorder (ER) Diagram. The ER program typically runs on a multi-core Linux server. It receives events from the Event Transfer system and writes them to the disk. It is possible to write several files in parallel to increase the writing performance; the event order is preserved in a process.

#### 980 5.9. Runtime Database (RCDB)

A JLab-designed MYSQL-based Runtime Database (RCDB) is used to store the run parameters and statis- 1030 tics. It has a web interface (see Fig. 29) and provides an interface to various languages including C++ and Java.

#### 985 5.10. Online Data Monitoring

The CLAS12 Online Data Monitoring system is the <sup>103</sup> set of programs attached to the Event Transfer system that processes data in real time. One such output of the program is shown in Fig. 30. The monitoring system al-

<sup>990</sup> lows shift takers to insert histograms into the electronic logbook. Every CLAS12 detector has a designated set <sup>1040</sup> of histograms that is closely monitored by shift takers and detector experts to ensure data quality.

#### 5.11. Electronic Logbook

The CLAS12 shift personal use the JLab Electronic Logbook [24], as web-based system that provides an interface to browse, search, and create electronic logbook entries. The system has been built using the Drupal content management system and utilizes a MySQL backend database to store its entries. The system has been designed to consolidate and replace the functionality of the multiple electronic logbook systems that existed at JLab between 1996 and 2012.

### 5.12. ROOT for DAQ (FT)

A ROOT-based system was developed to display integrated quantities from the CLAS Trigger system in the form of 1D and 2D histograms. The system is made by three different applications: a histogram sender running on each VTP, a histogram receiver running on a

<sup>1010</sup> DAQ server, and a user-configurable GUI client. Each histogram sender application defines a set of 1D and 2D histograms to report trigger data specific to the CLAS12 subsystem handled by the VTP it is running on. Histograms are refreshed at a fixed rate and streamed to the DAQ server in the form of JavaScript Object Notation (JSON) messages, exploiting the previously described ActiveMQ infrastructure. Each message contains: the histogram name, the number of bins, and a data array with the number of counts in each bin. The message receiver application is responsible for decoding these messages, and of creating ROOT histograms from them. Finally, the client application displays ROOT histograms to the user through a customizable GUI.

The GUI is composed of a programmable number of independent frames, with different histograms in each of them. Typically, each frame contains histograms related to the same CLAS12 subsystem. The GUI structure is specified through a configuration file passed as a command-line option when running the client. Communication between the message receiver/ROOT histogram produced application and the user client is handled through the ROOT TSocket mechanism. Figure 31 shows a GUI reporting histograms from the Forward Tagger system [20]: two 2D histograms showing the distribution of electromagnetic cluster hits in the Forward Tagger Calorimeter, and two 1D histograms showing the electromagnetic cluster energy distribution. The right (left) column reports histograms for electromagnetic clusters with (without) a matching hit in the Forward Tagger Hodoscope.

# 5.13. CLAS Event Display

The CLAS12 Event Display (ced) is a graphical application that displays events online (and offline) using various representations of CLAS12 called views. The views are independent windows that the user can pan, zoom, scroll, etc. Some of the views are geometrically faithful, and some are designed for maximal information content as opposed to realism. The primary purpose and utility of *ced*, when used online as part of the DAO system, is for additional data monitoring. While running, ced will display an event from the live stream at a selectable rate, typically one every two seconds. A quick glance at *ced* will confirm, for example, that there are data in the drift chambers that appear to form tracks. In this way it serves as an early warning of problems with detectors and/or the data stream. It is also possible to operate *ced* in a mode where it creates graphical histograms or occupancy overlays. A typical view from ced is shown in Fig. 32.

### 1060 6. Network

1065

The CLAS12 network is shown in Fig. 33. Its main 1085 component is an Arista router that serves as the backbone for the entire system. The set of primary DAQ servers is connected directly to the router by 40 Gb links. Some front-end components with particularly

- high data rates are connected directly to the router by 1090 10 Gb links. Most of the front-end components, as well as the workstations, are connected to multiple "leaf" network switches using 1 Gb links. These leaf switches
- <sup>1070</sup> are connected to the router by 10 Gb links. Two 40 Gb uplinks connect the entire CLAS12 system to the JLab Computer Center where data are sent for permanent storage to tape.

Most of the 1 Gb links use standard CAT6 copper

- <sup>1075</sup> cables, while the 10 Gb and 40 Gb links use optical fibers, with the exception of the shorter-range server <sup>1100</sup> links, where SFP and QSFP passive copper twinax cables are used.
- The CLAS12 network shows adequate performance and a high level of reliability. With the projected CLAS12 data rates, it can be used "as is" for the fore- 1105 seeable future.

#### 7. Slow Controls

The CLAS12 Slow Controls system was heavily upgraded for the 12 GeV era at JLab. It incorporates legacy and modern hardware and stand-alone controls systems into full EPICS [23] integration, such that everything is accessible from a single interface and on any computer in the CLAS12 system. Another important aspect is leveraging standard infrastructure tools supported by central JLab computing resources, for a manageable and reliable controls system. The CLAS12 Slow Controls system is based on Experimental Physics Industrial Control System (EPICS), currently version 3.14.12.5, and includes about 100 EPICS input-output controllers (IOCs) interfacing with approximately 50 different types of hardware via various communication protocols and over 800k process variables (PVs).

The controls system monitors and controls all aspects of the CLAS12 detector, beamline, and magnet systems, with monitoring on the DAQ system. This includes power supplies from a variety of manufacturers, programmable logic controllers, cryogenic and gas systems, multiple scaler hardware readout, flasher systems, all of the VXS crates, trigger system performance, and beamline motors, with sequencing for more com-

Figure 30: Online monitoring example. Only a small portion of the histograms is shown. The full set includes hundreds of histograms used by shift takers to monitor various detectors and subsystems.

Figure 31: Example of a ROOT-based GUI to monitor trigger data for the specific case of the Forward Tagger detector [20]. The top histograms report the distribution of electromagnetic cluster hit posi- 1130 tions, while the bottom histograms report the electromagnetic cluster energy distribution. The right (left) column reports histograms for electromagnetic clusters with (without) a matching hit in the Forward Tagger Hodoscope.

plex operations like polarimetry and magnet hysteresis. An example of the superconducting torus magnet nitrogen system and 10 kHz EPICS monitoring is shown in Fig. 34, and one of the scaler displays covering multiple

CLAS12 detector systems is shown in Fig. 35. 1140 Most of the IOCs run on standard rack-mounted servers running Red Hat Enterprise 7 (RHEL7) in the Counting House. A few IOCs run in more specialized systems in the experimental hall, such as VxWorks

- 1115 5.X real-time operating systems on Motorola VME 1145 controllers, primarily for high-rate, synchronous beam monitoring and support of legacy components. All IOCs and associated processes are managed with procServ for interactive access when necessary and cronjobs for au-
- 1120

1110

tomatic startup and recovery [25]. For the GUI we chose the modern Control Systems Studio (CS-Studio) developed at Oak Ridge National

Figure 32: ced event example that includes a schematic view of all detectors with a realistic geometry.

Laboratory [26]. CS-Studio is an Eclipse-based suite of tools for developing and monitoring large-scale control systems. It includes various features supporting quick interface development, such as templating and dynamic generation.

We also use the CS-Studio alarm system. It is based on a MYSQL database for storing alarm configurations, status, and message history, combined with a server monitoring the IOCs, updating the database, and communicating with clients. The clients include a graphical interface tightly integrated with the rest of the controls system, with visible feedback and a hierarchical view of the alarm system, an annunciator service running in the background in the Counting House, and a notifier service sending emails to on-call experts on particular alarm conditions.

Control system interfaces are all run locally on any desktop PC running RHEL7 in the Counting House. Full remote access is also provided via 2-factor authentication and X-forwarding or VNC, as well as VMWare virtual machines supported by JLab. Read-only access in a web browser is provided via WebOPI, another product affiliated with CS-Studio.

We utilize two internal EPICS channel access gateways, one read-only for the web interface, and the other for minimizing connections to superconducting magnet controls systems. Wherever appropriate, the standard autosave feature of EPICS is utilized to automatically preserve settings across IOC reboots, and the standard

1150

Figure 33: CLAS12 DAQ Network Diagram. All components and 1195 connections have adequate performance for the currently running and planned experiments.

Burt save/restore mechanisms. The controls system also utilizes many custom hardware and software interlocks.

1155

An important component of the Slow Controls system is archiving data. For this we utilize the EPICS archiving system called Mya, a product developed by and in support of accelerator operations at JLab and shared with the experimental halls. This provides storage and access to many previous years data of all CLAS12

EPICS PVs [27].

Installation and configuration of the associated desktop and server machines, including custom-service daemons, cron jobs, IOCs, network disk mounting, and deployment of upgrades and software changes, is managed

ployment of upgrades and software changes, is managed via puppet and a central server maintained by JLab [28]. 1210 The resulting maintenance is almost hands-free, and recovery from hardware failures or power outages is largely automated. Monitoring of the servers is performed with Nacion class provided by U set which pro-

formed with Nagios, also provided by JLab, which provides email notifications about system errors [29].

### 8. Performance

The CLAS12 DAQ performance was adequate during the first year of running. Thanks to high trigger purity, <sup>12</sup> the event rate never exceeded 20 kHz, which was easily handled by the DAQ with livetime above 93%. The data rate remains below 1000 MByte/s (see Fig. 24).

Several performance tests were conducted to check <sup>1225</sup> the data rate limits of the back-end components. With

the front-end and Event Builder excluded, the Event Transfer and Event Recorder showed a data rate exceeding 2 Gbyte/s on a single Dell R730 server. This demonstrates that the CLAS12 DAQ data rate limitation is much higher than required for all anticipated CLAS12 experiments.

# 9. Conclusions

Work on the CLAS12 DAQ system started in 2008 with design and implementation carried out in the period from 2008 to 2017. The system has been successfully used during the phase of development, testing, and commissioning of all of the CLAS12 detectors. In December 2017, the CLAS12 DAQ was ready for the first beam experiment and has been in full operation mode since that time. The performance achieved by the CLAS12 DAQ allows it to be used without significant changes for the entire CLAS12 physics program.

# 10. Acknowledgements

We are grateful to the administrative, engineering, and technical staff of JLab for constant support. In particular, we appreciate the hard work of the JLab Fast Electronics Group technical personnel: Mark Taylor, Armen Stepanyan, Jeff Wilson, and William Gunning. We also appreciate the contributions of the JLab Detector Support Group to the slow controls efforts. Our special thanks to the CLAS12 project leaders Volker Burkert and Latifa Elouadrhiri for leadership and setting goals. This material is based upon work supported by the U.S. Department of Energy, Office of Science, Office of Nuclear Physics under contract DE-AC05-06OR23177.
