74	(Dated: August 10, 2023)

(Dated: August 10, 2023)

The single-differential and fully integrated cross sections for quasi-free  $\pi^+\pi^-$  electroproduction off protons bound in deuterium have been extracted for the first time. The experimental data were collected at Jefferson Laboratory with the CLAS detector. The measurements were performed in the kinematic region of the invariant mass W from 1.3 GeV to 1.825 GeV and photon virtuality  $Q^2$  from 0.4 GeV<sup>2</sup> to 1.0 GeV<sup>2</sup>. Sufficient experimental statistics allow for narrow binning in all kinematic variables, while maintaining a small statistical uncertainty. The extracted cross sections were compared with the corresponding cross sections off free protons, which allowed us to obtain an estimate of the contribution from events in which interactions between the final-state hadrons and the spectator neutron took place.

INTRODUCTION I.

Exclusive reactions of meson photo- and electropro-77 duction off protons are intensively utilized in labora-78 tories around the world as a very powerful tool to in-79 vestigate nucleon structure and the principles of the 80 strong interaction. These studies include the extrac-81 tion of various observables from analyses of experi-82 mental data, as well as subsequent theoretical and <sup>113</sup> 83 phenomenological interpretations of the extracted ob-84 servables [1-3]. 85

PACS numbers: 11.55.Fv, 13.40.Gp, 13.60.Le, 14.20.Gk

Exclusive reactions off free protons have been stud-86 ied in considerable detail, and a lot of information 87 on differential cross sections and different single- and 88 double-polarization asymmetries with almost com-89 plete coverage of the reaction phase space has become 90 available. A large part of this information comes from 121 91 the analysis of data collected in Hall B at Jefferson 122 92 Lab (JLab) with the CLAS detector [4, 5]. 93

Meanwhile, reactions occurring in photon and elec-94 tron scattering off nuclei have been less extensively 95 investigated. Experimental information on these pro- 126 96 cesses is sparse and mostly limited to inclusive mea-97 surements of total nuclear photoproduction cross sec-98 tions [6–8] and the nucleon structure function  $F_2$  [9– 99 11], while exclusive measurements off bound nucleons 100 are lacking. 101

However, information on exclusive reactions off 132 102 bound nucleons is crucially important to the investiga-103 tion of nuclear structure and for a deeper understand-104

ing of the processes occurring in the nuclear medium because various exclusive channels will have different energy dependencies and different sensitivities to the reaction mechanisms. This situation creates a strong demand for exclusive measurements off bound nucleons, and the deuteron, being the lightest and most weakly bound nucleus, is the best target for initiating these efforts.

This paper presents the results of the data analysis of charged double-pion electroproduction off protons bound in a deuteron. The study became possible owing to the experiment of electron scattering off a deuterium target conducted in Hall B at JLab with the CLAS detector [4]. The description of the detector and target setup is given in Sec. II together with information on the overall data analysis strategy.

The analysis covers the second resonance region, where double-pion production plays an important role. The channel opens at the double-pion production threshold  $W \approx 1.22$  GeV, contributes significantly to the total inclusive cross section for  $W \lesssim$ 1.6 GeV, and dominates all other exclusive channels for  $W \gtrsim 1.6$  GeV.

Exclusive reactions off bound protons manifest some specific features that are not present in reactions off free protons and originate from (a) Fermi motion of the initial proton and (b) final state interactions (FSIs) of the reaction final hadrons with the spectator neutron. In this paper special attention is paid to the detailed description of these issues.

The paper introduces new information on the fully 189 135 integrated and single-differential cross sections of the 190 136 reaction  $\gamma_v p(n) \rightarrow p'(n') \pi^+ \pi^-$ . The cross section 191 137 measurements were performed in the kinematic region 192 138 of the invariant mass W from 1.3 GeV to 1.825 GeV 139 and photon virtuality  $Q^2$  from 0.4 GeV<sup>2</sup> to 1.0 GeV<sup>2</sup>. 140 Sufficient experimental statistics allow for narrow bin-141 ning, *i.e.* 25 MeV in W and 0.05 GeV<sup>2</sup> in  $Q^2$ , while 196 142 maintaining adequate statistical uncertainties. The 197 143 extracted cross sections are quasi-free, meaning that 144 the admixture of events, in which the final hadrons in-145 teracted with the spectator neutron, is kinematically 146 reduced to the achievable minimum. 147

The details of the cross section extraction analysis 148 are presented in Secs. III through VI, which encom-149 pass the selection of quasi-free events, the cross sec-150 tion calculation framework, the description of the cor-151 rections applied to the cross sections, and the study 152 of the cross section uncertainties. 153

Effects of the initial proton motion (also called 154 Fermi motion) turned out to be tightly interwoven 155 with many analysis aspects, and for this reason, their 156 description is scattered throughout the paper. Mean-157 while, FSI effects are addressed in a separate Sec-158 tion VII, which outlines specificities of FSIs in re-159 actions off bound protons and their differences from 160 FSIs in conventional free proton reactions. Some de-161 tails on FSI effects in this particular analysis are also 162 presented there. 163

Section VIII presents the measured cross sections 164 and their comparison with the cross section estimation 216 165 obtained based on the JLab-MSU<sup>1</sup> model JM, which 166 is a phenomenological reaction model for the process 167 of double-pion production off free protons [12–14]. 168

This study benefits from the fact that the free pro- 218 169 ton cross sections of the same exclusive reaction have 170 been recently extracted from CLAS data [15, 16]. 171 These free proton measurements were performed un-172 der the same experimental conditions as in this study, 173 including the beam energy value and the target setup. 174 For this reason, the free proton study [15, 16], was 175 naturally used as a reference point for many analysis 176 components. This unique advantage allows one not 177 only to verify the reliability of those analysis aspects 178 that are similar for reactions off free and bound pro-179 tons, but also to obtain a deeper understanding of 180 those that differ. The latter include the effects of the 181 initial proton motion and FSIs. 182

Section IX introduces a comparison of the cross 183 sections extracted in this study with their free pro-184 ton counterparts from Refs. [15, 16], which allowed us 185 to estimate the proportion of events in which FSIs 186 between the final hadrons and the spectator neutron 187 took place. Assuming the latter events to be the main 188

cause of the difference between the cross section sets. their contribution to the total number of the reaction events was found to vary in different regions of the reaction phase space, but in most parts of the phase space it maintains a level of 25%. Based on this comparison, other potential reasons that may contribute to the difference between the cross section sets can further be explored, which includes possible in-medium modifications of properties of nucleons and their excited states [6-8, 17, 18].

### **II. EXPERIMENT**

The electron scattering experiment that provided data for this study was conducted in Hall B at JLab as a part of the "e1e" run period. A longitudinally polarized electron beam was produced by the Continuous Electron Beam Accelerator Facility (CEBAF) and then was subsequently scattered off the target, which was located in the center of the CEBAF Large Acceptance Spectrometer (CLAS) [4]. This state-of-the-art detector covered a good fraction of the full solid angle and provided efficient registration of final-state particles originating from the scattering process.

The "e1e" run period lasted from November 2002 until January 2003 and included several experiments with different beam energies (1 GeV and 2.039 GeV) and target cell contents (liquid hydrogen and liquid deuterium). This study is devoted to the experiment conducted with the 2-cm-long liquid-deuterium target and utilizing a 2.039-GeV electron beam.

#### Α. Detector setup

The design of the CLAS detector was based on a toroidal magnetic field that was generated by six superconducting coils arranged around the beamline. The magnetic field bent charged particles towards or away from the beam axis (depending on the particle charge and the direction of the torus current) but left the azimuthal angle essentially unchanged. For this experiment, the torus field setting was to bend negatively charged particles towards the beamline (inbending configuration).

The magnet coils naturally separated the detector into six "sectors", each functioning as an independent magnetic spectrometer. Each sector included four sub-detectors: drift chambers (DC), Cerenkov counters (CC), time-of-flight system (TOF), and electromagnetic calorimeter (EC) [4].

The azimuthal coverage for CLAS was limited only by the magnet coils and was approximately 90% at backward polar angles and 50% at forward angles [19]. The polar angle coverage spanned from  $8^{\circ}$  to  $45^{\circ}$  for the Čerenkov counters and electromagnetic calorimeter and from  $8^{\circ}$  to  $140^{\circ}$  for the drift chambers and

<sup>&</sup>lt;sup>1</sup> JLab - Moscow State University (Russia) model.

the time-of-flight system. 241

The drift chambers were located within the region 242 of the magnetic field and performed charged particle 294 243 tracking, allowing for the determination of the par-244 ticle momentum from the curvature of their trajecto-245 ries. The other sub-detectors were located outside the 297 246 magnetic field region, which means that charged par-298 247 248 ticles traveled through them along a straight line [20].

The Cerenkov counters were located right behind 249 the DC and served the dual function of triggering on 250 electrons and separating electrons from pions [21]. 251

The TOF scintillators were located radially outside 252 the drift chambers and the Čerenkov counters but in 253 front of the calorimeter. The time-of-flight system 254 measured the time when a particle hit a TOF scintil-255 lator, thus allowing for the determination of its veloc-256 257 ity. Then, using the particle momentum known from the DC, its mass can be determined, meaning that the 258 particle can be identified [22, 23]. 259

The main functions of the electromagnetic 260 calorimeter were triggering on and detection of 261 electrons, as well as detection of photons (allowing 262 for the  $\pi^0$  and  $\eta$  reconstructions from their  $2\gamma$  decays) 263 and neutrons [19]. 264

The six CLAS sectors were equipped with a com-265 mon data-acquisition (DAQ) system that collected the 266 digitized data and stored the information for later off-267 line analysis. 268

### 269

#### Target setup В.

The "ele" target had a conical shape with the di-270 ameter varying from 0.35 to 0.6 cm, which served the 324 271 purpose of effective extraction of gas bubbles formed 272 in the liquid target content due to the heat that either 273 326 originated from the beam and/or came from outside 327 274 through the target walls. Due to the conical shape, 275 328 the bubbles drained upwards and into a wider area of 276 the target, thus clearing the beam interaction region 277 and allowing the boiled deuterium to be effectively 329 278 delivered back to the cooling system to be reliquified. 279

The target was located at -0.4 cm along the z axis 280 (near the center of CLAS) and its interaction region 281 was 2-cm-long. The target cell had  $15-\mu$ m-thick alu-282 minum entrance and exit windows. In addition, an 283 aluminum foil was located 2.0 cm downstream of the 284 target. This foil was made exactly to the same spec-285 ifications as the entry/exit windows of the target cell 286 and served for both the estimation of the number of 287 events that originated in the target windows and the 288 precise determination of the target z-position along 289 the beamline (see Sec. III D 3). 290

More details on the "ele" target assembly can be 341 291 found in Ref. [24]. 292 342

#### С. Data analysis strategy

Events corresponding to the investigated reaction  $ep(n) \rightarrow e'p'(n')\pi^+\pi^-$  were distinguished among all other detected events through the event selection procedure, described in detail in Sec. III. The selected exclusive events, however, represent only a part of the total number of events produced in the reaction, while the remainder were not registered due to (i) geometrical holes in the detector acceptance and (ii) less than 100% efficient particle detection within the detector acceptance. Therefore, to extract the reaction cross sections, the experimental event yield was adjusted for the geometric acceptance and detection efficiency. thereby accounting for the lost events.

In order to determine the overall detector efficiency, a Monte Carlo simulation was performed. In this analysis, double-pion events were generated with TWOPEG-D, which is an event generator for double-pion electroproduction off a moving proton [25]. These events are hereinafter called "generated" events.

The generated events were passed through a standard multi-stage procedure of simulating the detector response [4]. The procedure included the simulation of the particle propagation through the CLAS detector from the vertex produced by the event generator and the subsequent event reconstruction. Events that survived this process are hereinafter called "reconstructed" Monte Carlo events. They were analyzed in the same way as real experimental events.

#### III. QUASI-FREE EVENT SELECTION

For each event, the electron candidate was defined as the first-in-time particle that had signals in all four subcomponents of the CLAS detector (DC, CC, TOF, and EC). To select hadron candidates, signals only in two sub-detectors (DC and TOF) were required.

#### **Electron identification** Α.

To select good electrons among all electron candidates and to separate them from electronic noise, accidentals, and  $\pi^-$  contamination, the electromagnetic calorimeter (EC) and Cerenkov counter (CC) responses were analyzed.

According to Ref. [26], the overall EC resolution, as well as uncertainties from the EC output summing electronics, lead to fluctuations of the EC response near the hardware threshold. Therefore, to select only reliable EC signals, a minimal cut on the scattered electron momentum  $P_{e'}$  was applied in the software. The value of this cut was chosen to be 0.461 GeV, according to the relation suggested in Ref. [26].

To eliminate part of the pion contamination, a sam-343 381 pling fraction cut was applied based on the differ-344 ent energy deposition patterns of electrons and pions 345 in the EC. Specifically, when traveling through the 346 EC, an electron produces an electromagnetic shower, 347 where the deposited energy  $E_{\rm tot}$  is proportional to the 348 electron momentum  $P_{e'}$ , while a  $\pi^-$  loses a constant 349 amount of energy per scintillation layer independently 350 of its momentum. Therefore, for electrons the quan-351 tity  $E_{\text{tot}}/P_{e'}$  plotted as a function of  $P_{e'}$  is expected to 352 follow a straight line parallel to the x-axis and located 353 around the value 1/3 on the *y*-axis, since electrons lose 354

about 2/3 of their energy in the EC lead sheets. 355

FIG. 1. EC sampling fraction distribution for the experimental data for CLAS sector 1. The vertical line shows the position of the minimum momentum cut, while the other two curves correspond to the sampling fraction cut.

Figure 1 shows the EC sampling fraction  $(E_{tot}/P_{e'})$ 356 plotted as a function of the particle momentum for the 357 experimental data. In this figure, the cut on the min-358 imal scattered electron momentum is shown by the 359 vertical line, while the other two curves correspond 360 to the sampling fraction cut that was determined via 361 Gaussian fits to individual momentum slices of the 362 distribution. 363

To further improve the quality of the electron se-364 lection and  $\pi^{-}/e^{-}$  separation, the Čerenkov counter 365 response was analyzed [21]. Figure 2 illustrates pho-366 toelectron distributions measured in the CC for CLAS 367 sector 3. As seen in Fig. 2, contamination is present in 368 the measured CC spectra in the form of a peak located 369 at values of a few photoelectrons. The contamination 370 is thought to originate from accidental coincidences of 371 photomultiplier tube (PMT) noise signals with mea-372 sured pion tracks [27]. The goal of the event selection 373 in the CC was to separate the spectrum of good elec-374 tron candidates from the contamination peak, while 375 minimizing the loss of good events. To achieve this 376 goal, the following set of CC cuts was applied: 377

- fiducial cut in the CC, 378
- $\varphi_{\rm cc}$  matching cut, 379
- $\theta_{\rm cc}$  matching cut, 380

- geometrical cut that removes inefficient zones, and
- cut on the number of photoelectrons.

415

Each of these cuts, except the last one, was defined in the "CC projective plane" [27], wherein the polar and azimuthal angles  $(\theta_{cc}, \varphi_{cc})$  were defined. The details on the plane definition and angle calculations can be found in Refs. [27, 28].

The shape of the fiducial cut in the CC plane was taken from Ref. [29]. The  $\varphi_{cc}$  and  $\theta_{cc}$  matching procedures were based on the studies [27] and [30] and relied on the anticipation that for real events, there must be a one-to-one correspondence between PMT signals in the CC and the angles in the CC plane (which are calculated from the DC information), while background noise and accidentals should not show such a correlation.

FIG. 2. Influence of different CC cuts on the photoelectron distributions for CLAS sector 3. Curves from top to bottom: black curve - only fiducial cut in the CC plane is applied, red curve – the  $\varphi_{cc}$  matching cut is added, blue curve – the  $\theta_{cc}$  matching cut is added, and green curve – the geometrical cut that removes inefficient CC zones is added.

The idea of the  $\varphi_{cc}$  matching cut is that the particle track on the right side of the CC segment should match with the signal from the right-side PMT, and vice versa. Events that do not satisfy these conditions were removed. Events with signals from both PMTs were kept.

To perform  $\theta_{cc}$  matching, a  $\theta_{cc}$  versus segment number cut was applied. Figure 3 shows the  $\theta_{cc}$  versus segment distribution for CLAS sector 2. Event distributions in each segment have been plotted as a function of  $\theta_{cc}$  and fit with Gaussians. The horizontal black lines correspond to the positions of the fit maxima  $\pm 4\sigma$ . Events between these black lines were treated as good electron candidates.

Another important issue is that some specific geometrical zones in the CC showed low detection efficiency. When an electron hit such a zone, the number of detected photoelectrons was significantly less than

FIG. 3.  $\theta_{cc}$  versus CC segment distributions for CLAS sector 2. Events between the horizontal black lines were treated as good electron candidates.

483

expected. This leads to a systematic overpopulation 416 of the low-lying part of the photoelectron spectrum 417 and enhances the contamination peak. Since low effi-418 ciency zones were distributed inhomogeneously in the 419 CC plane and the Monte Carlo simulation did not 420 reproduce them properly, a geometrical cut that re-421 moves inefficient zones was applied. The details on 422 this cut can be found in Refs. [15, 16, 28, 31]. 423

The influence of the above cuts on the photoelec-424 tron distributions is demonstrated in Fig. 2, where 425 the distribution before the matching cuts is plotted 426 in black, after the  $\varphi_{cc}$  matching – in red, and after 427 the subsequent  $\theta_{cc}$  matching cut – in blue. As seen 428 in Fig. 2, the matching cuts reduce the contamination 429 peak, but do not affect the main part of the photo-430 electron spectrum. Finally, the green distribution is 431 plotted after adding the cut that removes inefficient 432 CC zones. As expected, this cut leads to an event 433 reduction in the low-lying part of the photoelectron 434 spectrum, including the region of the contamination 435 peak, while leaving the high-lying part of the spec-436 trum essentially unchanged. 437

The applied cuts result in a significant reduction 470 438 of the contamination peak and its better separation 471 439 from the main spectrum. As a final step, a cut on 472 440 the number of photoelectrons was applied, which al-441 together eliminates the remains of the contamination 474 442 443 peak. The cut position was individually optimized for each PMT for each CC segment for each CLAS sector. 444 As the Monte Carlo did not reproduce photoelectron 445 distributions well enough, the cut was performed only 446 on the experimental data. To recover good electrons 447 lost in this way, a standard procedure was applied, 448 which is based on the fit of the photoelectron distri-449 butions by a modified Poisson function. More details 450 on the procedure can be found in Refs. [15, 16, 28, 31]. 451

### 452

#### в. Hadron identification

Hadrons were identified through the timing infor-485 453 mation provided by the TOF System [22, 23], which 486 454

allowed the velocity  $(\beta_h = v_h/c)$  of the hadron candidates to be determined.

A charged hadron can be identified by comparing  $\beta_h$  determined from TOF information with  $\beta_{\rm n}$  given 458 by

$$\beta_{\rm n} = \frac{p_h}{\sqrt{p_h^2 + m_h^2}}.\tag{1}$$

In Eq. (1)  $\beta_n$  is termed the nominal value and was calculated using the particle momentum  $(p_h)$  known from the DC and the exact particle mass assumption  $(m_h).$ 

FIG. 4.  $\beta_h$  versus momentum distributions for positive pion candidates. The thin black curve in the middle of the event band corresponds to the nominal  $\beta_n$  given by Eq. (1). The red curves show the applied hadron identification cuts. Events between the red curves were treated as good pion candidates.

Experimental  $\beta_h$  versus momentum distributions were examined for each TOF scintillator for each CLAS sector. This examination revealed that for some scintillation counters, the distributions were either shifted from their nominal positions or showed a double-band structure. To correct the timing information for such counters, a special procedure, described in Refs. [28, 31], was developed. In addition, a few counters were found to give unreliable signals; they were removed from consideration for both experimental data and simulation.

Figure 4 shows the  $\beta_h$  versus momentum distribution for positive pion candidates plotted for all sectors and all reliable scintillators. The event band of pion candidates is clearly seen. The red curves show the applied identification cuts. Events between the red curves were selected for further analysis. Analogous identification cuts were performed for the proton and negative pion candidates.

#### $\mathbf{C}.$ Momentum corrections

While traveling through the detector and the target, the final-state particles lose a part of their energy due to interactions with the medium. As a result,

the measured particle momentum appears to be lower 541 487

than the actual value. In the investigated kinematic 488

region, this effect is pronounced only for low-energy 543 489 protons, while for all other detected particles it is in-544 490 significant. 491 545

The simulation of the CLAS detector correctly 492 propagates particles through the media and, there-493 fore, the effect of the energy loss is already included 494 in the efficiency and does not impact the extracted 495 cross sections. Nevertheless, in this study, the pro-496 ton momentum magnitude was corrected for the en-497 ergy loss. The simulation of the CLAS detector was 498 used to establish the correction function, which was 499 then applied for both experimental and reconstructed 500 Monte Carlo events [28, 31]. 501

Additionally, Ref. [32] provides evidence that parti-502 cle momenta and angles may have some small system-503 atic deviations from their real values due to slight mis-504 alignments in the DC position, small inaccuracies in 555 505 the description of the torus magnetic field, and other 556 506 possible reasons. The magnitude of this effect de-507 pends on the particle momentum, increasing as the 508 momentum grows. In the investigated kinematic re-509 gion, the effect was discernible only for scattered elec-510 trons. 511

Due to the undefined origin of the above effect, it 512 cannot be simulated, and therefore, it has become 513 conventional for CLAS data analyses to apply a spe-514 cial momentum correction to the experimental data. 515 This particular study uses the electron momentum 516 corrections that have previously been developed and 517 tested in the analysis of the free proton part of the 518 "ele" dataset at the same beam energy [15, 16]. To 519 establish them, the approach [32], which was based 520 on elastic kinematics, was used. These corrections in-521 clude an electron momentum magnitude correction as 522 well as an electron polar angle correction, which were 523 developed for each CLAS sector individually. 524

525

#### D. Other cuts

### 526

#### 1. Fiducial cuts

The active detection solid angle of the CLAS de-527 579 tector was smaller than  $4\pi$ , in part due to the space 528 occupied by the torus field coils. This is to say that 529 the angles covered by the coils were not equipped with 580 530 any detection system and therefore formed a "dead" 581 531 area for particle detection [4]. Additionally, the detec-582 532 tion area was further limited in the polar angle from 583 533  $8^{\circ}$  up to  $45^{\circ}$  for electrons and up to  $140^{\circ}$  for other 584 534 charged particles [4]. 535

Furthermore, as was shown in different data anal-536 yses, the edges of the active detection area also do 537 not provide a safe region for particle reconstruction, 538 being affected by rescattering from the coils, field dis-539 tortions, and similar effects. Therefore, it has be-540

come common practice to exclude these regions from consideration by applying specific fiducial cuts. This method guarantees that events accepted in the analysis include only particles detected in "safe" areas of the detector, where the acceptance is well understood.

In this study, fiducial cuts were applied for all four final-state particles  $(e', p', \pi^+, \text{ and } \pi^-)$  for both experimental events and reconstructed Monte Carlo events. The analytical shapes of the cuts are similar to those used in the analysis of the free proton part of "ele" dataset at the same beam energy [15, 16], and more details can be found in Refs. [28, 31].

#### Data quality checks 2.

During a long experimental run, variations of the experimental conditions, e.g. fluctuations in the target density, deviations in the beam current and position, and/or changes in the detector response can lead to fluctuations in event yields. To select for the analvsis only the parts of the run with relatively stable event rates, cuts on the data-acquisition (DAQ) live time and the number of events per Faraday cup (FC) charge were used.

The FC charge updated with a given frequency, so the whole run time can be divided into "blocks". Each block corresponds to the portion of time between two FC charge readouts. The DAQ live time is the portion of time within the block during which the DAQ system was able to accumulate events. A significant deviation of the live time from the average value indicates event rate alterations.

To establish data quality check cuts, the DAQ live time, as well as the yields of inclusive and elastic events normalized to the FC charge, were examined as a function of block number. Those blocks for which these quantities demonstrated large fluctuations were excluded from the analysis. In this study, the quality check cuts are similar to those used in Refs. [15, 16]. For more details see also Refs. [28, 31].

#### 3. Vertex cut

The analyzed dataset included runs with the target cell filled with liquid deuterium, as well as runs with the empty target cell. The latter are needed to account for background events produced by the electron scattering off the target windows.

Figure 5 presents the distributions of the electron z-coordinate at the interaction vertex for events from full and empty target runs (black and magenta curves, respectively). Both distributions are normalized to the corresponding charge accumulated in the Faraday cup. The value of the vertex coordinate z is corrected

8

for the effects of beam-offset<sup>2</sup> [28, 31]. Both distri- 619 591 butions in Fig. 5 demonstrate a well-separated peak 592 620 around  $z_{e'} = 2.6$  cm originating from the downstream 593 aluminum foil. The distribution of events from the 621 594 empty target runs shows two other similar peaks that 595 correspond to the entrance and exit windows of the 622 596 target cell (see also Sec. IIB). 597 623

FIG. 5. Distributions of the electron z-coordinate at the vertex for full (black curve) and empty (magenta curve) target runs for CLAS sector 4. Vertical red lines show the applied cuts. Both the full and empty target distributions are normalized to the corresponding FC charge.

Empty target events were passed through the same 598 selection procedure that was established for the liquid-599 deuterium data and eventually were subtracted from 600 the latter as shown in Sec. IV E. In addition to the 601 empty target event subtraction, a cut on the electron 602 z-coordinate was applied. This cut is shown by the 603 two vertical lines in Fig. 5: events outside these lines 604 were excluded from the analysis. 605

### E. Exclusivity cut in the presence of Fermi smearing and FSIs

608

### 1. Reaction topologies

To identify a certain exclusive reaction, one needs 609 to register the scattered electron and either all final 610 hadrons or all except one. In the latter case, the four-611 momentum of the unregistered hadron can be deduced 612 using energy-momentum conservation. Thus for the 613 reaction  $ep \rightarrow e'p'\pi^+\pi^-$  one can, in general, distin-614 guish between four "topologies" depending on the spe-615 cific combination of registered final hadrons. In this 616 particular analysis, the following two topologies were 617 analyzed, 618

- the fully exclusive topology (all final particles registered)  $ep \rightarrow e'p'\pi^+\pi^- X$ , and
- the  $\pi^-$  missing topology  $ep \to e'p'\pi^+X$ .

670

671

672

673

674

The statistics of the fully exclusive topology are very limited, mainly because CLAS did not cover the polar angle range  $0^{\circ} < \theta_{\text{lab}} < 8^{\circ}$  [4]. In this experiment, the presence of this forward acceptance hole mostly impacted registration of the negative particles (e and  $\pi^-$ ) as their trajectories were bent by the torus magnetic field towards the beam axis. This lead to a constraint on the minimum achievable  $Q^2$  for electrons and prevented registration of the majority of negative pions. As a consequence, the  $\pi^-$  missing topology contains the dominant part of the statistics. The contribution of the fully exclusive topology to the total analyzed statistics varies from ~5% near the reaction threshold to ~25% at W between 1.7 and 1.8 GeV.

Besides the limited statistics, the fully exclusive topology also suffers from limited acceptance and therefore from a very large number of empty cells (see Sec. V A for more details on empty cells). These circumstances do not allow for any sensible cross section information to be obtained from this topology alone. The  $\pi^-$  missing topology has a tolerable number of empty cells and large statistics, and therefore serves the purpose of the cross section extraction best.

In general, two more topologies can be distinguished, *i.e.* the proton missing topology and the  $\pi^+$ missing topology. Both require registration of the  $\pi^$ in the final state and as a result suffer from similar issues of suppressed statistics and limited acceptance as the fully exclusive topology. These two topologies are typically ignored in analyses of the reaction  $ep \rightarrow e'p'\pi^+\pi^-$  [33–37]. Nevertheless, as demonstrated in a previous analysis of this reaction off free protons [15, 16], all four reaction topologies can be used in combination, which allows for an increase in the statistics and a reduction in the number of empty cells.

However, if the pion pair was produced off the proton bound in deuterium, these two additional topologies turn out to be contaminated with events from other reactions. Specifically, in the proton missing topology, the missing particle reconstruction fails to determine whether the pion pair was produced off the proton or off the neutron because their masses are almost identical. A similar situation occurs for the  $\pi^+$ missing topology, where one can hardly distinguish between the production of a  $\pi^+\pi^-$  pair off the proton and a  $\pi^0 \pi^-$  pair off the neutron, if only the proton and the  $\pi^{-}$  in the final state were registered. Furthermore, the  $\pi^+$  missing topology also has a strong admixture of events from the reaction  $en(p) \to e'p'(p')\pi^-$ . These circumstances prevented the use of the proton missing and the  $\pi^+$  missing topologies in this analysis.

<sup>&</sup>lt;sup>2</sup> The beam offset is the deviation of the beam position from the CLAS central line (x, y) = (0, 0) that can lead to the inaccurate determination of the vertex position.

Most notably, exclusive reactions off bound protons 733 675 have the following features that are not present in 676 734 reactions off free protons: (a) Fermi motion of the 735 677 initial proton and (b) final state interactions (FSIs) of 736 678 the reaction final hadrons with the spectator neutron. 737 679 These features introduce some complications into the 738 680 exclusive event selection, as discussed below. 681 739

Since the momentum of the initial proton was not 740 682 experimentally measured, this analysis uses the so-741 683 called "target-at-rest assumption" for calculation of 742 684 some kinematic quantities (such as missing mass, re-685 action invariant mass W, etc.). This leads to the 744 686 Fermi smearing of the corresponding experimental 745 687 distributions [38]. To reliably identify the exclusive 688 channel and correctly estimate the detector efficiency, 747 689 a good match between the distributions of experi-690 mental events and reconstructed Monte Carlo events 691 should be observed. This demands the simulated dis-692 tributions reproduce the Fermi smearing of the exper-693 imental distributions, which implies that the effects 694 of initial proton motion are properly included in the 695 Monte Carlo simulation. 696

For this reason, the Monte Carlo simulation in this 697 analysis was performed using the TWOPEG-D [25] 698 event generator, which simulates the quasi-free pro-699 cess of double-pion electroproduction off a moving 700 proton. This is an extension of TWOPEG, which is 701 the event generator for double-pion electroproduction 702 off the free proton [39]. For the TWOPEG-D version 703 of the event generator, the Fermi motion of the ini-704 tial proton is generated according to the Bonn poten-705 tial [40] and then is merged, in a natural way, into the 706 specific kinematics of double-pion electroproduction. 707 FSIs of the reaction final hadrons with the specta-708 tor nucleon introduce the second intrinsic feature of 709 exclusive reactions off bound nucleons. Such interac-710 tions alter the total four-momentum of the reaction fi-711 nal state and therefore, introduce distortions into the 712 distributions of some kinematic quantities (such as 713 missing masses), thus complicating the identification 758 714 of a specific exclusive channel [41] (see also Sec. VII B). 715 In contrast to the effects of the initial proton mo-716 tion, which can be simulated fairly easily, the FSI ef-717 fects can hardly be taken into account in the simu-718 lation because of their complex nature. The Monte 719 Carlo simulation is hence not able to reproduce the 720 distortions of some experimental distributions caused 721 by FSIs with the spectator. For this reason, a proper 722 procedure for isolation of quasi-free events from the 723 FSI-background had to be developed. 724

The yield of events in FSI-disturbed kinematics 725 turned out to strongly depend on (i) the reaction in-726 variant mass W and (ii) the hadron scattering angles. 727 The latter issue causes FSI effects to manifest them-728 selves differently depending on the reaction topology, 729 since the topologies have nonidentical geometrical ac-730 ceptance (see Sec. VIIC). For this reason, the channel 731 identification was performed in each topology individ-732

ually, as described in the next subsections.

775

776

Finally, the issue of background channels should also be addressed. For the double-pion production off free protons, the main background channel is  $ep \rightarrow$  $e'p'\pi^+\pi^-\pi^0$ . The analysis [15, 16] that was carried out for the same beam energy  $E_{beam} = 2.039 \text{ GeV}$ demonstrated that although the admixture of the events from this background channel becomes discernible at  $W \gtrsim 1.6$  GeV, it remains negligible and well separated from the double-pion events via the exclusivity cuts. For the double-pion production off protons in deuterium, one more background channel can be distinguished, which is  $en(p) \to e'p'(p')\pi^+\pi^-\pi^-$ , but background events from this channel follow the same kinematic pattern as events from the aforementioned  $ep \to e'p'\pi^+\pi^-\pi^0$  reaction.

#### Fully exclusive topology 2.

To isolate quasi-free double-pion events in the fully exclusive topology, the distributions of the quantities determined by Eq.(2) were used. The missing momentum  $P_X$  and the missing mass squared  $M^2_{X[0]}$  are defined for the reaction  $ep(n) \to e'p'(n')\pi^+\pi^-X$ , where X corresponds to the undetected part.

$$P_X = |\vec{P}_e - \vec{P}_{e'} - \vec{P}_{p'} - \vec{P}_{\pi^+} - \vec{P}_{\pi^-}|$$

$$M_{X[0]}^2 = [P_e^{\mu} + P_p^{\mu} - P_{e'}^{\mu} - P_{p'}^{\mu} - P_{\pi^+}^{\mu} - P_{\pi^-}^{\mu}]^2$$
(2)

Here  $P_i^{\mu}$  are the four-momenta and  $\overrightarrow{P_i}$  the threemomenta of particle i. Both quantities were calculated under the target-at-rest assumption, *i.e.* considering  $P_p^{\mu} = (0, 0, 0, m_p)$  with the proton rest mass  $m_p$ .

The quantities  $P_X$  and  $M^2_{X[0]}$  are unique for the fully exclusive topology as they can be calculated only if all final hadrons were registered. Figure 6 presents the distributions of  $P_X$  (left plot) and  $M^2_{X[0]}$ (right plot) for experimental data (in black) and Monte Carlo simulation (in blue) in a 100-MeV-wide bin in W.

As seen in Fig. 6, the simulated  $P_X$  distribution perfectly matches the experimental one for  $P_X$  < 0.2 GeV, while for  $P_X > 0.2$  GeV the simulation underestimates the data. The mismatch mainly originates from experimental events in which final hadrons interacted with the spectator neutron. The contribution from such events cannot be reproduced by the Monte Carlo simulation as the latter does not include FSI effects. The background channels, also not included in the Monte Carlo, contribute to the mismatch. too.

The cut on the missing momentum  $P_X$  was applied to select exclusive events in quasi-free kinematics, and the cut value was chosen to be  $P_X = 0.2$  GeV. To further clean up the sample of selected events, the cut on the missing mass squared  $M_{X[0]}^2$  was applied

FIG. 6. Distributions of the quantities  $P_X$  (left) and  $M^2_{X[0]}$ (right) defined in Eq. (2) plotted for experimental data (black) and Monte Carlo simulation (blue) in one 100-MeV-wide bin in W. Vertical red lines indicate the cuts applied for the selection of exclusive quasi-free events. The plotted quantities as well as the values of W were calculated under the target-at-rest assumption. The distributions are normalized to their maxima.

complementing the cut on the missing momentum. 777 The cuts are shown in Fig. 6 by the vertical red lines. 778 It is noteworthy that although in the fully exclu-779 sive topology the four-momentum of the  $\pi^-$  was mea-780 sured, it was not used in the subsequent calculation 781 of kinematic variables for the cross section extraction. 782 The measured four-momentum was instead replaced 783 by the one that was calculated as missing (and thus 784 was Fermi smeared) to achieve consistency with the 785 main  $\pi^-$  missing topology. 786

787

### 3. $\pi^-$ missing topology

In the  $\pi^-$  missing topology, the quantities  $P_X$  and  $M^2_{X[0]}$  defined in Eq. (2) are not available due to incomplete knowledge of the reaction final state. The channel identification was therefore performed using the four-momentum  $P^{\mu}_{X[\pi^-]}$  for the reaction  $ep(n) \rightarrow$ 810  $e'p'(n')\pi^+X$ , which was calculated as

$$P_{X[\pi^{-}]}^{\mu} = P_{e}^{\mu} + P_{p}^{\mu} - P_{e'}^{\mu} - P_{p'}^{\mu} - P_{\pi^{+}}^{\mu}, \qquad (3)$$

where  $P_i^{\mu}$  are the four-momenta of particle *i* and *X* 814 788 815 corresponds to the undetected part. 789

To isolate quasi-free events in the  $\pi^-$  missing topology, a special procedure was developed, in which the following quantity was used to perform the exclusivity cut,

$$M_{X[\pi^{-}]} = \sqrt{|[P^{\mu}_{X[\pi^{-}]}]^{2}|}.$$
 (4)

Figure 7 shows the distribution of the quantity 817 790  $M_{X[\pi^{-}]}$  plotted for the experimental data (black his-791 togram) and Monte Carlo simulation (blue histogram) 792 819 in one 25-MeV-wide W bin. The magenta histogram 793 shows the difference between them and thus repre-820 794 sents the distribution of background events, which 821 795

are mainly events affected by FSIs with the spectator. The green line corresponds to the cut applied to select quasi-free events. 798

FIG. 7. Distributions of the quantity  $M_{X[\pi^{-}]}$  (defined by Eq. (4) in one 25-MeV-wide W bin for the experimental data (black histogram), Monte Carlo simulation (blue histogram), and their difference (magenta histogram). The explanation of the fit curves is given in the text. The green line shows the applied exclusivity cut.

As seen in Fig. 7, the exclusivity cut does not allow for complete isolation of the quasi-free event sample. Tightening the cut would lead to significant reduction in the statistics of selected events, yet without total elimination of the FSI-background. Therefore, an "effective correction" of the FSI-background admixture was performed, which included the following steps.

- The  $M_{X[\pi^{-}]}$  distribution of the reconstructed Monte Carlo events (blue histogram) was fit with a polynomial. A typical result of this fit is shown in Fig. 7 by the solid orange curve.
- The magenta background distribution was fit with a Gaussian. The result of the fit is shown by the dark-magenta dash-dotted curve.
- The orange and dark-magenta curves were summed up to produce the red dashed curve that matches the black experimental histogram.
- The correction factor  $F_{\text{FSI}}$  was determined for the left side of the green cut line,

$$F_{\text{FSI}}(W) = \frac{\text{area under the orange curve}}{\text{area under the red curve}} \le 1.$$
 (5)

• In each W bin, the experimental event yield was multiplied by the factor  $F_{\text{FSI}}$ , which served as an effective correction due to the remaining admixture of the FSI-background events.

The factor  $F_{\text{FSI}}$  is assumed to be only W dependent as it was not found to exhibit any  $Q^2$  dependence,

and the dependence on the final hadronic variables is 822 870 neglected due to the statistics limitation. The value 823 871 of  $F_{\rm \scriptscriptstyle FSI}$  varies from  ${\sim}0.97$  to  ${\sim}0.93$  for the W bins 872 824

in the range from 1.45 GeV to 1.825 GeV. For W <825

1.45 GeV, the correction is not needed as no mismatch 826

between the experimental and simulated distributions 873 827 is observed in this region (see Sec. VIIC). 828

Note that the exclusivity cut shown in Fig. 7, ac-829 companied by the corresponding correction, accounts 830 for all other possible effects that along with the FSI 831 effects may contribute to the mismatch between the 832 data and the simulation in this topology (including 833 the minor three-pion background contribution). 834

#### CROSS SECTION CALCULATION IV. 835

#### Fermi smearing of the invariant mass WΑ. 836

For the process of double-pion electroproduction off 837 protons (as for any other exclusive process), the re-838 action invariant mass can, in general, be determined 839 in two ways, *i.e.* either from the initial particle four-840 momenta  $(W_i)$  or from the final particle four-momenta 841  $(W_{\rm f})$  as Eqs. (6) and (7) demonstrate. 842

$$W_{\rm i} = \sqrt{(P_p^{\mu} + P_{\gamma_v}^{\mu})^2}$$
(6)

$$W_{\rm f} = \sqrt{(P^{\mu}_{\pi^+} + P^{\mu}_{\pi^-} + P^{\mu}_{p'})^2} \tag{7}$$

Here  $P^{\mu}_{\pi^+}$ ,  $P^{\mu}_{\pi^-}$ , and  $P^{\mu}_{p'}$  are the four-momenta of the final-state hadrons,  $P^{\mu}_{p}$  is the four-momentum of the initial proton and  $P^{\mu}_{\gamma_{v}} = P^{\mu}_{e} - P^{\mu}_{e'}$  the four-843 844 845 momentum of the virtual photon with  $P_e^{\mu}$  and  $P_{e'}^{\mu}$ 846 the four-momenta of the incoming and scattered elec-847 trons, respectively. 848

In general, to determine  $W_{\rm f}$ , all final hadrons should 849 be registered, while for the calculation of  $W_i$ , it is suffi-850 cient to register just the scattered electron. The latter 851 option allows one to analyze event samples in which 852 information on the reaction final state is incomplete, 853 906 as *e.g.* in topologies with one unregistered final hadron 854 907 855 (see Sec. III E). However, in reactions off bound nucle-908 ons, this opportunity comes with a complication as to 856 909 correctly calculate  $W_i$ , information on the initial pro-857 ton momentum  $(P_p^{\mu})$  is also required. In this analysis, 858 910 however, this information is not accessible in the  $\pi^-$ 859 missing topology. This situation brings up the choice 912 860 to either demand registration of all final hadrons to 913 861 determine  $W_{\rm f}$  (which reduces the analysis flexibility) 862 914 or to calculate  $W_i$  assuming the initial proton to be 915 863 at rest. 864

In this analysis, the invariant mass  $W_i$  calcu-917 865 lated under the target-at-rest assumption was used 918 866 to describe the reaction, based on the statistically 867 919 dominant  $\pi^-$  missing topology. For this reason, 920 868 the extracted cross sections turn out to be Fermi 921 869

smeared [25, 38]. To retrieve the non-smeared observable, a correction that unfolds this effect should be applied, which is described in Sec. VC.

Once the double-pion events were selected as described in Section III, the laboratory four-momenta of all final particles are known as they are either registered or reconstructed as missing. These fourmomenta were then used to calculate the kinematic variables, which are introduced in Sec. IV C.

The cross sections were extracted in the centerof-mass frame of the virtual photon – initial proton system (CMS). Therefore, to calculate the kinematic variables, the four-momenta of all particles need to be transformed from the laboratory system (Lab) to the CMS.

The CMS is uniquely defined as the system where the initial proton and the photon move towards each other with the  $z_{CMS}$ -axis pointing along the photon and the net momentum equal to zero. However, the procedure of the Lab to CMS transformation differs depending on the specificity of the reaction initial state (real or virtual photons, at rest or moving initial proton).

The correct procedure of the Lab to CMS transformation for an electroproduction experiment off a moving proton can be subdivided into two major steps.

- 1. First, one needs to perform a transition to the auxiliary system, where the target proton is at rest, while the incoming electron moves along the z-axis. This system can be called "quasi-Lab", since the initial conditions of the reaction in this frame imitate those existing in the Lab system in the case of the free proton experiment. The recipe of the Lab to quasi-Lab transformations is given in detail in Ref. [25].
- 2. Then, the quasi-Lab to CMS transformation should be performed by the standard method used for an electroproduction experiment off a proton at rest [15, 16, 28, 31].

The first step of this procedure (Lab to quasi-Lab transformation) implies that the momentum of the initial proton is known for each reaction event [25]. In this analysis, however, information on the initial proton momentum can be accessible only in the fully exclusive topology (it can be deduced via momentum conservation as shown in Sec. III E 2), while in the  $\pi^{-}$ missing topology, this information turns out to be irrevocably lost due to incomplete knowledge about the reaction final state. As a result, for the majority of the analyzed events, the correct Lab to CMS transformation could not be performed. For this reason,

in this analysis, the procedure of Lab to CMS trans-922 formation for an electroproduction experiment off a 923 proton at rest was used. The procedure is described 924 in Refs. [15, 16, 28, 31] and was employed for both fully 925 exclusive and  $\pi^-$  missing topologies for consistency. 926

This approximation in the Lab to CMS transfor-927 mation introduces a systematic inaccuracy to the ex-928 tracted cross sections. A correction for this effect is 929 included in the procedure of unfolding the effects of 930 the initial proton motion (see Sec. VC). 931

#### С. Kinematic variables

Once the four-momenta of all particles were defined 933 and transformed into the CMS, the kinematic vari-934 ables that describe the reaction  $ep(n) \rightarrow e'p'(n')\pi^+\pi^-$ 935 were calculated. To define the reaction initial state, 936 only two variables are needed. In this study, they were 937 chosen to be the reaction invariant mass W and the  $_{986}$ 938 photon virtuality  $Q^2$ . 939

Meanwhile, the three-body final hadron state of the 940 reaction is unambiguously determined by five kine-941 matic variables [15], and in general there can be dif-942 ferent options for their choice. In this analysis, the 943 following generalized set of variables was used [14– 944 16, 28, 31, 36, 37, 42]: 945

- invariant mass of the first pair of hadrons  $M_{h_1h_2}$ , 946
- invariant mass of the second pair of hadrons 947  $M_{h_2h_3}$ , 948
- the first hadron solid angle  $\Omega_{h_1} = (\theta_{h_1}, \varphi_{h_1})$ , and 949
- the angle  $\alpha_{h_1}$  between the two planes (i) de-950 fined by the three-momenta of the virtual pho-951 ton (or initial proton) and the first final hadron 952 and (ii) defined by the three-momenta of all final 953 hadrons. 954

In this study, the cross sections were obtained in 955 three sets of variables depending on various assign-956 ments for the first, second, and third final hadrons: 957

958 1. 
$$[p', \pi^+, \pi^-] M_{p'\pi^+}, M_{\pi^+\pi^-}, \theta_{p'}, \varphi_{p'}, \alpha_{p'},$$

959 2. 
$$[\pi^-, \pi^+, p'] M_{\pi^-\pi^+}, M_{\pi^+p'}, \theta_{\pi^-}, \varphi_{\pi^-}, \alpha_{\pi^-}, \text{and}$$

960 3. 
$$[\pi^+, \pi^-, p'] M_{\pi^+\pi^-}, M_{\pi^-p'}, \theta_{\pi^+}, \varphi_{\pi^+}, \alpha_{\pi^+}.$$

Details on the calculation of the kinematic vari-961 ables from the particle four-momenta can be found 962 in Refs. [15, 28, 31, 36]. 963

964

932

#### Binning and kinematic coverage D.

The available kinematic coverage in the initial state 965 variables is shown by the  $Q^2$  versus W distribution 966

in Fig. 8. This distribution is filled with the doublepion events that survived after the event selection described in Sec.III. The white boundary limits the analyzed kinematic area, where the double-pion cross sections were extracted. The black grid demonstrates the chosen binning in the initial state variables (25 MeV in W and 0.05 GeV<sup>2</sup> in  $Q^2$ ).

992

993

994

995

996

997

The kinematic coverage in the final state variables has the following reaction-related features. The angular variables  $\theta_{h_1}$ ,  $\varphi_{h_1}$ , and  $\alpha_{h_1}$  vary in the fixed ranges of  $[0, \pi]$ ,  $[0, 2\pi]$ , and  $[0, 2\pi]$ , respectively. Meanwhile, the ranges of the invariant masses  $M_{h_1h_2}$  and  $M_{h_2h_3}$ are not fixed - they are W dependent and broaden as W grows.

The binning in the final hadronic variables used in this study is specified in Table I. In each W and  $Q^2$ bin, the full range of each final hadronic variable was divided into bins of equal size. The number of bins differs in various W subranges in order to take into account (i) the statistics drop near the reaction threshold and (ii) the aforementioned broadening of the reaction phase space with increasing W. The chosen number of bins in each considered W subrange reflects the intention to maintain reasonable statistical uncertainties of the single-differential cross sections for all W and  $Q^2$  bins.

FIG. 8.  $Q^2$  versus W distribution populated with the selected double-pion events. The cross section was calculated in 2D cells within the white boundaries.

For the binning in the polar angle, the reader should note the following. The cross section, although being differential in  $[-\cos\theta]$ , is binned in  $\theta$ . These  $\Delta\theta$  bins are of equal size in each corresponding W subrange. See also Sec. IV E on this matter.

The specific organization of the double-pion production phase space in the invariant masses  $(M_{h_1h_2}, M_{h_2h_3})$  impels the need to pay careful attention to the binning in these variables. Equation (8)exemplifies the expressions for the lower and upper boundaries of the  $M_{h_1h_2}$  distribution and demonstrates that the upper boundary depends on the value

	Hadronic variable	[1.3, 1.35]	W subr [1.35, 1.4]	cange (GeV) [1.4, 1.475]	[1.475, 1.825]
$M_{h_1h_2}$	Invariant mass	8	10	12	12
$M_{h_2h_3}$	Invariant mass	8	10	12	12
$\theta_{h_1}$	Polar angle	6	8	10	10
$\varphi_{h_1}$	Azimuthal angle	5	5	5	6
$\alpha_{h_1}$	Angle between planes	5	6	8	8
	Total number of $\Delta^5 \tau$ cells in a $\Delta W \Delta Q^2$ bin	9600	24000	57600	69120

TABLE I. Number of bins for hadronic variables.

of W, while the lower does not.

$$M_{\text{lower}} = m_{h_1} + m_{h_2}$$

$$M_{\text{upper}}(W) = W - m_{h_3}$$
(8)

Here  $m_{h_1}$ ,  $m_{h_2}$ , and  $m_{h_3}$  are the rest masses of the final hadrons.

Since the cross section is calculated in W bins of  $_{1025}$ 1000 a given width, the boundary of  $M_{\rm upper}$  is not dis-  $_{\rm ^{1026}}$ 1001 tinct. For the purpose of binning in mass, the value of  $_{1027}$ 1002  $M_{\rm upper}$  was calculated using  $W_{\rm center}$ , at the center of 1028 1003 the W bin, which caused events with  $W > W_{center}$  to 1004 be located beyond  $M_{upper}$ . For this reason, it was de-1005 cided to use a specific arrangement of mass bins with 1030 1006 the bin width  $\Delta M$  determined by 1031 1007

$$\Delta M = \frac{M_{\rm upper} - M_{\rm lower}}{N_{\rm bins} - 1},$$
 (9) 1034  
1035

where  $N_{\rm bins}$  is the number of bins specified in the first row of Table I. The left boundary of the first bin was set to  $M_{\rm lower}$ .

The chosen arrangement of bins forces the last bin 1039 1011 to be situated completely out of the boundaries cal-1012 1040 culated according to Eq. (8) using  $W_{\text{center}}$ . The cross 1013 1041 section in this extra bin is not reported. However, this 1014 bin was kept in the analysis since its contents (though 1015 1042 being very small) contribute to all cross sections that 1016 1043 were obtained by integrating over the corresponding 1017 invariant mass distribution. 1018 1044

Note that the cross section in the next to last bin <sup>1045</sup>
 in invariant mass needs a correction. See more details <sup>1046</sup>
 in Sec. V D.

1022 E. Cross section formula

### 1023 1. Electron scattering cross section

The experimental electron scattering cross section  $_{1054}$  $\sigma_e$  for the reaction  $ep(n) \rightarrow e'p'(n')\pi^+\pi^-$  is seven-fold  $_{1055}$  differential and determined by

$$\frac{\mathrm{d}^{7}\sigma_{e}}{\mathrm{d}W\mathrm{d}Q^{2}\mathrm{d}^{5}\tau} = \frac{1}{R\cdot\mathcal{F}}\cdot\frac{\left(\frac{N_{\mathrm{full}}}{Q_{\mathrm{full}}} - \frac{N_{\mathrm{empty}}}{Q_{\mathrm{empty}}}\right)}{\Delta W\cdot\Delta Q^{2}\cdot\Delta^{5}\tau\cdot\left[\frac{l\cdot\rho\cdot N_{A}}{q_{e}\cdot\mu_{d}}\right]\cdot\mathcal{E}},\tag{10}$$

where

1032

1036

1048

1049

1050

1051

1052

1053

- $d^5\tau = dM_{h_1h_2}dM_{h_2h_3}d\Omega_{h_1}d\alpha_{h_1}$  is the differential of the five independent variables of the  $\pi^+\pi^-p$  final state, which are described in Sec. IV C;
- N<sub>full</sub> and N<sub>empty</sub> are the numbers of selected double-pion events inside the seven-dimensional bin for runs with liquid deuterium and empty target, respectively;
- the quantity in the square brackets in the denominator corresponds to the luminosity (per charge) of the experiment  $\mathcal{L}$  in the units cm<sup>-2</sup>·C<sup>-1</sup> and its components are

$$\begin{split} l = &2 \mbox{ cm} \mbox{ the target length}, \\ \rho = &0.169 \mbox{ g} \cdot \mbox{cm}^{-3} \mbox{ the liquid-deuterium density}, \\ N_A = &6.022 \cdot 10^{-19} \mbox{ mol}^{-1} \mbox{ Avogadro's number}, \\ q_e = &1.602 \cdot 10^{-19} \mbox{ C the elementary charge, and} \\ \mu_d = &2.014 \mbox{ g} \cdot \mbox{mol}^{-1} \mbox{ the deuterium molar mass}, \end{split}$$

which results in the luminosity value of  $\mathcal{L} = 0.63 \cdot 10^{42} \text{ cm}^{-2} \cdot \text{C}^{-1} = 0.63 \cdot 10^{12} \ \mu \text{b}^{-1} \cdot \text{C}^{-1};$ 

- $Q_{\text{full}} = 3734.69 \ \mu\text{C}$  and  $Q_{\text{empty}} = 464.797 \ \mu\text{C}$  are the values of the integrated Faraday cup charge for liquid-deuterium and empty-target runs, respectively, which results in the corresponding values of the integrated luminosity  $L = \mathcal{L} \cdot Q$  of  $2.35 \cdot 10^9 \ \mu\text{b}^{-1}$  and  $0.29 \cdot 10^9 \ \mu\text{b}^{-1}$ ;
- $\mathcal{E} = \mathcal{E}(\Delta W, \Delta Q^2, \Delta^5 \tau)$  is the detector efficiency (which includes the detector acceptance) for each seven-dimensional bin as determined by the Monte Carlo simulation (see Sec. IV F);
- $R = R(\Delta W, \Delta Q^2)$  is the radiative correction factor described in Sec. V B;

•  $\mathcal{F} = \mathcal{F}(\Delta W, \Delta Q^2, \Delta^5 \tau)$  is the correction factor that aims at unfolding the effects of the initial proton motion (see Sec. V C).

### 1059 2. Virtual photoproduction cross section

1056

1057

1058

The goal of the analysis was to extract the virtual photoproduction cross section  $\sigma_{\rm v}$  of the reaction  $\gamma_v p(n) \rightarrow p'(n')\pi^+\pi^-$ . This virtual photoproduction cross section  $\sigma_{\rm v}$  is five-fold differential and in the single-photon exchange approximation is connected with the seven-fold differential electron scattering cross section  $\sigma_e$  via

$$\frac{d^{5}\sigma_{v}}{d^{5}\tau} = \frac{1}{\Gamma_{v}} \frac{d^{7}\sigma_{e}}{dW dQ^{2} d^{5}\tau} , \qquad (11) \frac{1071}{1072}$$

1070

1074

1075

1096

1097

1098

1099

1100

1101

1102

1103

1104

1105

1106

1107

1108

1109

where  $\Gamma_{\rm v}$  is the virtual photon flux given by

$$\Gamma_{\rm v}(W,Q^2) = \frac{\alpha}{4\pi} \frac{1}{E_{\rm beam}^2 m_p^2} \frac{W(W^2 - m_p^2)}{(1 - \varepsilon_{\rm T})Q^2} \,.$$
(12)

Here  $\alpha$  is the fine structure constant (1/137),  $m_p^{1077}$ the proton mass,  $E_{\text{beam}} = 2.039$  GeV the energy of the incoming electrons in the Lab frame, and  $\varepsilon_{\text{T}}$  the <sup>1078</sup> virtual photon transverse polarization given by <sup>1079</sup>

$$\varepsilon_{\rm T} = \left(1 + 2\left(1 + \frac{\nu^2}{Q^2}\right) \tan^2\left(\frac{\theta_{e'}}{2}\right)\right)^{-1}, \quad (13)_{1082}^{1081}$$

where  $\nu = E_{\text{beam}} - E_{e'}$  is the virtual photon energy, <sup>1084</sup> 1060 while  $E_{e'}$  and  $\theta_{e'}$  are the energy and the polar angle of 1085 1061 the scattered electron in the Lab frame, respectively. 1086 1062 The limited statistics of the experiment do not al- 1087 1063 low for estimates of the five-fold differential cross sec- 1088 1064 tion  $\sigma_{\rm v}$  with reasonable accuracy. Therefore, the cross 1089 1065 section  $\sigma_{\rm v}$  was first obtained on the multi-dimensional 1090 1066 grid and then integrated over at least four hadronic 1091 1067 variables, which means that only single-differential 1092 1068 and fully integrated cross sections were obtained. 1093 1069

For each W and  $Q^2$  bin, the following cross sections <sup>1094</sup> were extracted for each set of variables (see Sec. IV C), <sup>1095</sup>

$$\begin{aligned} \frac{\mathrm{d}\sigma_{\mathrm{v}}}{\mathrm{d}M_{h_{1}h_{2}}} &= \int \frac{\mathrm{d}^{5}\sigma_{\mathrm{v}}}{\mathrm{d}^{5}\tau} \mathrm{d}M_{h_{2}h_{3}} \mathrm{d}\Omega_{h_{1}} \mathrm{d}\alpha_{h_{1}}, \\ \frac{\mathrm{d}\sigma_{\mathrm{v}}}{\mathrm{d}M_{h_{2}h_{3}}} &= \int \frac{\mathrm{d}^{5}\sigma_{\mathrm{v}}}{\mathrm{d}^{5}\tau} \mathrm{d}M_{h_{1}h_{2}} \mathrm{d}\Omega_{h_{1}} \mathrm{d}\alpha_{h_{1}}, \\ \frac{\mathrm{d}\sigma_{\mathrm{v}}}{\mathrm{d}[-\cos\theta_{h_{1}}]} &= \int \frac{\mathrm{d}^{5}\sigma_{\mathrm{v}}}{\mathrm{d}^{5}\tau} \mathrm{d}M_{h_{1}h_{2}} \mathrm{d}M_{h_{2}h_{3}} \mathrm{d}\varphi_{h_{1}} d\alpha_{h_{1}}, \end{aligned}$$

$$\frac{\mathrm{d}\sigma_{\mathrm{v}}}{\mathrm{d}\alpha_{h_1}} = \int \frac{\mathrm{d}^5 \sigma_{\mathrm{v}}}{\mathrm{d}^5 \tau} \mathrm{d}M_{h_1 h_2} \mathrm{d}M_{h_2 h_3} \mathrm{d}\Omega_{h_1}, \text{ and}$$

$$\sigma_{\mathbf{v}}^{\text{int}}(W,Q^2) = \int \frac{d^5 \sigma_{\mathbf{v}}}{\mathrm{d}^5 \tau} \mathrm{d}M_{h_1 h_2} \mathrm{d}M_{h_2 h_3} \mathrm{d}\Omega_{h_1} \mathrm{d}\alpha_{h_1}.$$
(14)

As a final result for each W and  $Q^2$  bin, the fully 1110 integrated cross section  $\sigma_v^{\text{int}}$ , averaged over the three 1111 variable sets, is reported together with the nine singledifferential cross sections given in Eq. (15), where each column is taken from the corresponding variable set.

$$\frac{\mathrm{d}\sigma_{\mathrm{v}}}{\mathrm{d}M_{p'\pi^{+}}} \qquad \frac{\mathrm{d}\sigma_{\mathrm{v}}}{\mathrm{d}M_{\pi^{-}\pi^{+}}} \qquad \frac{\mathrm{d}\sigma_{\mathrm{v}}}{\mathrm{d}M_{\pi^{-}p'}}$$

$$\frac{\mathrm{d}\sigma_{\mathrm{v}}}{\mathrm{d}[-\cos\theta_{p'}]} \qquad \frac{\mathrm{d}\sigma_{\mathrm{v}}}{\mathrm{d}[-\cos\theta_{\pi^{-}}]} \qquad \frac{\mathrm{d}\sigma_{\mathrm{v}}}{\mathrm{d}[-\cos\theta_{\pi^{+}}]} \quad (15)$$

$$\frac{\mathrm{d}\sigma_{\mathrm{v}}}{\mathrm{d}\alpha_{p'}} \qquad \frac{\mathrm{d}\sigma_{\mathrm{v}}}{\mathrm{d}\alpha_{\pi^{-}}} \qquad \frac{\mathrm{d}\sigma_{\mathrm{v}}}{\mathrm{d}\alpha_{\pi^{+}}}$$

Regarding the middle row in Eq. (15), note the following. Although being differential in  $[-\cos\theta]$ , the cross sections were calculated in  $\Delta\theta$  bins, which are of equal size in the corresponding W subrange (see also Sec. IV D). This follows the convention used to extract the  $\theta$ -distributions in studies of double-pion cross sections [15, 16, 33–37, 43].

### F. Efficiency evaluation

In this study, the Monte Carlo simulation was performed using the TWOPEG-D event generator [25], which is capable of simulating the quasi-free process of double-pion electroproduction off a moving proton. In this event generator, the Fermi motion of the initial proton is generated according to the Bonn potential [40] and then is naturally merged into the specific kinematics of double-pion electroproduction. TWOPEG-D accounts for radiative effects according to the approach described in Refs. [39, 44].

Events generated with TWOPEG-D were passed through the standard detector simulation and reconstruction procedures with the majority of parameters kept the same as in the studies [15, 16, 45–47], which were also devoted to the "e1e" run period. More information on the simulation/reconstruction procedure and the related parameters can be found in Ref. [28].

In studies of double-pion production cross sections, it is important to generate enough Monte Carlo statistics in order to saturate each multi-dimensional bin of the reaction phase space with events (see Table I). Insufficient Monte Carlo statistics will lead to an improper efficiency evaluation and an unnecessary rise in the number of empty cells (see Sec. V A), thus systematically affecting the accuracy of the extracted cross sections. For this study, about  $4 \cdot 10^{10}$  double-pion events were generated in the investigated kinematic region, which was found to be sufficient.

TWOPEG-D performs a weighted event generation [39], which means that all kinematic variables are randomly generated according to the double-pion production phase space, while each event generated at a particular kinematic point acquires an individual weight that reflects the cross section value at that <sup>1112</sup> point. The efficiency factor  $\mathcal{E}$  from Eq. (10) was then <sup>1158</sup> <sup>1113</sup> calculated in each  $\Delta W \Delta Q^2 \Delta^5 \tau$  bin by <sup>1159</sup>

$$\mathcal{E}(\Delta W, \Delta Q^2, \Delta^5 \tau) = \frac{\mathbb{N}_{\text{rec}}}{\mathbb{N}_{\text{gen}}} = \frac{\sum_{i=1}^{N_{\text{rec}}} w_i}{\sum_{j=1}^{N_{\text{gen}}} w_j}, \qquad (16)^{1163}_{1164}$$

1160

1199

1200

1201

1202

1203

1205

1167 where  $N_{\text{gen}}$  is the number of generated double-pion 1114 1168 events (without any cuts) inside a multi-dimensional 1115 1160 bin and  $N_{\rm rec}$  is the number of reconstructed double-1116 1170 pion events that survived in the bin after the event 1117 1171 selection, while  $\mathbb{N}_{\text{gen}}$  and  $\mathbb{N}_{\text{rec}}$  are the weighted num-1118 1172 bers of the corresponding events and w is the weight 1119 1173 of an individual event. 1120 1174

In some kinematic bins, the efficiency  $\mathcal{E}$  could 1121 1175 not be reliably determined due to boundary effects. 1122 1176 bin-to-bin event migration, and limited Monte 1123 1177 Carlo statistics. In such bins, the relative efficiency 1124 1178 uncertainty  $\delta \mathcal{E}/\mathcal{E}$  is typically large. In this study, 1125 1179 a cut on the relative efficiency uncertainty  $\delta \mathcal{E}/\mathcal{E}$ 1126 1180 was performed that excluded from consideration all 1127 1181 multi-dimensional cells with uncertainties greater 1128 1182 than 30%. The excluded cells were ranked as "empty 1129 1183 cells" and, along with other empty cells, were subject 1130 1184 to the filling procedure (see Sec. VA). 1131 1185

The cut on the relative efficiency uncertainty di-1132 1186 rectly impacts the cross section uncertainties. On the 1133 1187 one hand, it eliminates the  $\Delta^5 \tau$  bins with large  $\delta \mathcal{E}/\mathcal{E}$ 1134 1188 values, thus reducing the total statistical uncertainty 1135 1189 of the extracted cross sections (see Sec. VIA). On 1136 1190 the other hand, this cut increases the number of 1137 1191 empty cells, thus increasing the cross section model 1138 1192 dependence and the uncertainty associated with 1139 1193 it (see Sec. VIB). The cut value was chosen as a 1140 1194 compromise between these two effects. 1141 1195

<sup>1142</sup> The idea of this cut has been taken from the <sup>1143</sup> <sup>1143</sup> study [15, 16], which also sets the cut value at 30%. <sup>1196</sup> <sup>1144</sup> More details can be found in Refs. [15, 16, 28, 31]. <sup>1198</sup>

# 1145 V. CORRECTIONS TO THE CROSS 1146 SECTIONS

### 1147 A. Filling kinematic cells with zero acceptance 1204

1206 Due to blind areas in the geometrical coverage 1148 of the CLAS detector, some kinematic bins of the 1149 double-pion production phase space turn out to have 1150 zero acceptance. In such bins, which are usually called <sup>1207</sup> 1151 empty cells, the cross section cannot be experimen-1152 tally defined. These cells contribute to the integrals 1208 1153 in Eqs. (14) along with the other kinematic bins. If 1209 1154 ignored, the contribution from these cells causes a 1210 1155 systematic underestimation of the cross section and, 1211 1156 therefore, some assumptions for the empty cell con-1212 1157

tents are needed. This situation causes some model dependence of the extracted cross sections.

The map of the empty cells was determined using the Monte Carlo simulation. A multi-dimensional cell was treated as empty if it contained generated events  $(N_{\rm gen} > 0)$ , but did not contain any reconstructed events  $(N_{\rm rec} = 0)$ . The cells with unreliable efficiencies, ruled out based on the 30% cut on the efficiency uncertainty, were also treated as empty (see Sec. IV F).

For studies of double-pion cross sections with CLAS, it has become conventional to fill the empty cells by means of a Monte Carlo event generator in order to account for their contribution. See more details in Refs. [15, 16, 33–37, 43].

In the present work, empty multi-dimensional cells were filled with the Monte Carlo events generated with TWOPEG-D [25]. These events were subject to integral scaling, in order to adjust them to the experimental yield in the regular (non-empty) cells. The scaling was performed individually in each  $\Delta W \Delta Q^2$ bin according to the ratio of the integrated yields of the experimental and reconstructed Monte Carlo events in the non-empty cells [28, 31].

Figure 9 introduces the single-differential cross sections given by Eqs. (14) and (15). The empty squares correspond to the case when the contribution from the empty cells was ignored, and the black circles are for the case when that was taken into account as described above. The figure indicates a satisfactory small contribution from the empty cells for the majority of data points (and therefore a small model dependence of the results). Only the edge points in the  $\theta$  distributions (middle row) reveal pronounced contributions due to the negligible/zero CLAS acceptance in the corresponding directions.

For most of the  $(W, Q^2)$  points, the contribution from the empty cells to the fully integrated cross section is kept to a low level of ~15%, slightly rising at the low  $Q^2$  and high W boundaries. Besides this, the empty cell contribution grows towards the threshold (*i.e.* for  $W \leq 1.4$  GeV). This behavior was also observed in Refs. [15, 16, 35, 36] devoted to double-pion electroproduction off the free proton.

To account for the model dependence, the approach established for the previous studies of double-pion cross sections was followed [15, 37, 48], *i.e.* the part of the single-differential cross section that came from the empty cells is assigned a 50% relative uncertainty (more details are in Sec. VI B).

### B. Radiative corrections

The incoming and scattered electrons are subject to radiative effects, which means that they can emit photons, thereby reducing their energy. Information on such emissions is typically experimentally inaccessible, and therefore, these changes in electron energy

FIG. 9. Extracted single-differential cross sections for the cases when the contribution from the empty cells was ignored (empty squares) and when it was taken into account (black circles). The former are reported with the uncertainty  $\delta_{\text{stat}}^{\text{tot}}$  given by Eq. (22), while the latter are with the uncertainty  $\delta_{\text{stat},\text{mod}}^{\text{tot}}$  given by Eq. (26). All distributions are given for one particular bin in W and  $Q^2$  (W =1.6375 GeV,  $Q^2$  =0.625 GeV<sup>2</sup>).

cannot be directly taken into account in the cross section calculation. As a result, measured cross sections
acquire distortions.

The common way of handling this problem is to 1237 1216 apply radiative corrections to the extracted cross sec- 1238 1217 1218 tions. In this study, the radiative corrections were <sup>1239</sup> performed using TWOPEG-D [25], which is the event <sup>1240</sup> 1219 generator for the double-pion electroproduction off a 1241 1220 moving proton. TWOPEG-D accounts for the ra- 1242 1221 diative effects by means of the well-known Mo and 1243 1222 Tsai approach [44], which has traditionally been used 1244 1223 for the radiative corrections in studies of double-pion<sup>1245</sup> 1224 electroproduction [15, 16, 33–37, 43]. In Ref. [44], the 1246 1225 approach was applied to the inclusive case, while in 1247 1226 TWOPEG-D, the fully integrated double-pion cross 1248 1227 sections are used instead [25, 39]. 1249 1228

In the employed approach [25, 39, 44], the radia-<sup>1250</sup> tive photons are considered to be emitted collinearly <sup>1251</sup> either in the direction of the incoming or scattered electron (termed the "peaking approximation"). The calculation of the radiative cross section is split into two parts. The "soft" part assumes the energy of the emitted radiative photon to be less than a certain minimal value (10 MeV), while the "hard" part is for the photons with an energy greater than that value. The "soft" part is evaluated explicitly, while for the calculation of the "hard" part, an inclusive hadronic tensor is assumed. Based on previous experience, the latter assumption is considered to be adequate [15, 16, 33– 37, 43]. Also note that approaches that are capable of describing radiative processes in exclusive double-pion electroproduction are not yet available.

The radiative correction factor R in Eq. (10) was determined in the following way. Double-pion events either with or without radiative effects were generated with TWOPEG-D. Both radiated and non-radiated events were subjected to the Fermi smearing. Then the ratio given by Eq. (17) was taken in each  $\Delta W \Delta Q^2$ bin.

$$R(\Delta W, \Delta Q^2) = \frac{\mathbb{N}_{\text{rad}}}{\mathbb{N}_{\text{norad}}}$$
(17)

FIG. 10. Reciprocal of the radiative correction factor  $^{1301}$  (*i.e.* 1/R) as a function of W for different  $Q^2$  bins (see  $^{1302}$  Eq. (17)).

1304

1305

1306

1315

1316

1318

This approach gives the correction factor R only as 1256 a function of W and  $Q^2$ , disregarding its dependence 1257 on the hadronic variables. However, the need to inte-1258 grate the cross section at least over four hadronic vari-1259 ables (see Eq. (14)) considerably reduces the influence 1260 of the final-state hadron kinematics on the radiative 1261 correction factor, thus justifying the applicability of 1262 the procedure [25, 39, 44]. 1263

The quantity 1/R is plotted in Fig. 10 as a function of W for different  $Q^2$  bins. The uncertainties associated ated with the statistics of generated events are very small and therefore not visible in the plot.

# $_{1268}$ C. Unfolding the effects of initial proton motion $_{1317}$

In this study, information on the initial proton mo- 1319 1269 mentum is inaccessible for the majority of analyzed 1320 1270 experimental events, as discussed above. For this 1321 1271 reason, the invariant mass  $W_i$  calculated under the <sup>1322</sup> 1272 target-at-rest assumption has to be used for the cross 1323 1273 section binning (see Sec. IVA), which leads to the 1324 1274 Fermi smearing of both the fully integrated and single-1325 1275 differential cross sections. The same reason necessi- 1326 1276 tates the use of an approximate procedure of the Lab 1327 1277 to CMS transformation (see Sec. IV B). This approx-1328 1278 imation introduces some inaccuracy to the measured 1279 angular  $(\theta, \varphi, \text{ and } \alpha)$  distributions without having 1280 an impact on the invariant mass distributions and W  $_{\rm ^{1329}}$ 1281 and  $Q^2$  cross section dependencies due to the Lorentz 1282 invariance of the corresponding variables. 1283 1330

Being folded with the aforementioned effects of 1331 the initial proton motion, the extracted cross sec- 1332

tions require a corresponding unfolding correction. This correction was performed by means of two Monte Carlo event generators TWOPEG [39] and TWOPEG-D [25]. TWOPEG is the event generator for the double-pion electroproduction off the free proton that currently provides the best cross section estimation in the investigated kinematic region. TWOPEG-D is the event generator for the same exclusive reaction but off the proton that moves in the deuterium nucleus. This event generator was specifically developed to be used in the studies where experimental information on the initial proton momentum is inaccessible, and one has to work under the target-at-rest assumption. TWOPEG-D convolutes the double-pion cross section with effects of the initial proton motion and thus imitates the conditions of the experimental cross section extraction.

To calculate the correction factor, two samples of double-pion events, produced off protons at rest and off moving protons, were generated with TWOPEG and TWOPEG-D, respectively. For the latter, the smeared value of W was used for the binning and the approximate Lab to CMS transformation was applied, so that the sample incorporates the same inaccuracies as the experimentally extracted cross sections.

The unfolding correction was performed in each multi-dimensional bin of the double-pion production phase space, *i.e.* in each  $\Delta W \Delta Q^2 \Delta^5 \tau$  bin the cross section was divided by the correction factor  $\mathcal{F}$  that was calculated as

$$\mathcal{F}(\Delta W, \Delta Q^2, \Delta^5 \tau) = \frac{\mathbb{N}_{\text{fermi}}}{\mathbb{N}_{\text{nofermi}}},$$
(18)

where  $\mathbb{N}_{\text{nofermi}}$  and  $\mathbb{N}_{\text{fermi}}$  are the weighted numbers of generated double-pion events in the  $\Delta W \Delta Q^2 \Delta^5 \tau$ bin produced off the proton at rest and off the moving proton, respectively.

This correction mostly affects the cross section near the reaction threshold, while for higher W its impact is small [28, 31].

The value of the correction factor in Eq. (18) depends on both the free proton cross sections and the model of the deuteron wave function that are employed in the event generators. The former relies strongly on the JM model fit of the available data on the double-pion cross sections, while for the latter, the Bonn model was used (see Refs. [25, 39] for more detail). Therefore, the uncertainty of the extracted cross sections that comes from this unfolding correction was attributed to the model-dependent uncertainty as discussed in Sec. VI B.

### D. Corrections for binning effects

In general, being extracted in a finite bin, the cross section naturally undergoes averaging within this bin, and this averaged value is then assigned to the bin

central point. Any nonlinear behavior of the cross 1370 1333 section within the bin will likely result in an offset 1371 1334 of the obtained cross section value. To cure this ef- 1372 1335 fect, a binning correction was applied that includes 1373 1336 a cubic spline approximation for the cross section 1374 1337 shape [28, 31]. Due to the relatively fine binning in all 1375 1338 kinematic variables used in this study, the influence of 1376 1339 the binning effects on the cross sections is marginal: 1377 1340 the typical value of the correction is  $\sim 1\%$  rising up to 1341 5% for some data points at low W. 1342

In addition to that, the cross section in the next 1343 to last point of the invariant mass distributions was 1344 subject to a specific separate correction, which is de-1345 scribed in detail in Refs. [15, 16, 28, 31]. The need 1346 for this correction follows from the broadening of the <sup>1378</sup> 1347 reaction phase space with W, which causes the upper <sup>1379</sup> 1348 boundary of the invariant mass distributions to be W1380 1349 dependent. 1381 1350 1382

# 1351 VI. CROSS SECTION UNCERTAINTIES

In this study (like in other studies of the doublepion cross sections [15, 16, 33–37, 43]) three separate
types of cross section uncertainties were considered, *i.e.* statistical uncertainties, uncertainties due to the
model dependence, and systematic uncertainties.

1357

### A. Statistical uncertainties

The limited statistics of both the experimental data <sup>1388</sup> and the Monte Carlo simulation are the two sources of <sup>1389</sup> statistical fluctuations of the extracted cross sections. <sup>1390</sup>

The absolute statistical uncertainty due to the limited statistics of the experimental data was calculated in the non-empty multi-dimensional bins as <sup>1391</sup>

$$\delta_{\text{stat}}^{\text{exp}}(\Delta^{5}\tau) = \frac{1}{\mathcal{E} \cdot R \cdot \mathcal{F} \cdot \Gamma_{\text{v}}} \cdot \frac{\sqrt{\left(\frac{N_{\text{full}}}{Q_{\text{full}}^{2}} + \frac{N_{\text{empty}}}{Q_{\text{empty}}^{2}}\right)}}{\Delta W \cdot \Delta Q^{2} \cdot \Delta^{5}\tau \cdot [\mathcal{L}]}, \quad (19)_{1394}^{1393}$$

where  $\Gamma_{\rm v}$  is the virtual photon flux given by Eq. (12), <sup>1396</sup> while the other variables are explained in the context <sup>1397</sup> of Eq. (10).

The absolute uncertainty due to the limited Monte 1399 Carlo statistics was estimated in the non-empty bins 1400 as

$$\delta_{\text{stat}}^{\text{MC}}(\Delta^5 \tau) = \frac{\mathrm{d}^5 \sigma_{\rm v}}{\mathrm{d}^5 \tau} \left(\frac{\delta \mathcal{E}}{\mathcal{E}}\right), \qquad (20)^{\frac{1402}{1403}}_{\frac{1404}{1405}}$$

<sup>1364</sup> where  $\frac{d^5 \sigma_v}{d^5 \tau}$  is the virtual photoproduction cross sec-<sup>1406</sup> tion given by Eq. (11),  $\mathcal{E}$  is the efficiency inside the <sup>1407</sup> <sup>1366</sup> multi-dimensional bin defined by Eq. (16), and  $\delta \mathcal{E}$  is <sup>1408</sup> <sup>1409</sup> the absolute statistical efficiency uncertainty. <sup>1409</sup>

<sup>1368</sup> The calculation of the efficiency uncertainty  $\delta \mathcal{E}$  <sup>1410</sup> <sup>1369</sup> is not straightforward because (i)  $N_{\rm gen}$  and  $N_{\rm rec}$  in <sup>1411</sup> 18

Eq. (16) are not independent and (ii) Monte Carlo events in this equation are subject to weighting. Therefore, the special approach described in Ref. [49] was used to calculate  $\delta \mathcal{E}$ . Neglecting the event migration between bins, this approach gives the following expression for the absolute statistical uncertainty of the efficiency in a bin for the case of a weighted Monte Carlo simulation,

$$\delta \mathcal{E}(\Delta^5 \tau) = \sqrt{\frac{\mathbb{N}_{\text{gen}} - 2\mathbb{N}_{\text{rec}}}{\mathbb{N}_{\text{gen}}^3} \sum_{i=1}^{N_{\text{rec}}} w_i^2 + \frac{\mathbb{N}_{\text{rec}}^2}{\mathbb{N}_{\text{gen}}^4} \sum_{j=1}^{N_{\text{gen}}} w_j^2},\tag{21}$$

where  $N_{\text{gen}}$  and  $N_{\text{rec}}$  are the number of the generated and reconstructed Monte Carlo events inside the multi-dimensional bin, respectively,  $\mathbb{N}_{\text{gen}}$  and  $\mathbb{N}_{\text{rec}}$  are the corresponding weighted event numbers, and w is the weight of an individual event.

The two parts of the statistical uncertainty given by Eqs. (19) and (20) were combined quadratically into the total absolute statistical uncertainty in each non-empty  $\Delta^5 \tau$  bin,

$$\delta_{\text{stat}}^{\text{tot}}(\Delta^5 \tau) = \sqrt{\left(\delta_{\text{stat}}^{\text{exp}}\right)^2 + \left(\delta_{\text{stat}}^{\text{MC}}\right)^2}.$$
 (22)

The cross section assigned to the empty  $\Delta^5 \tau$  cells acquires zero statistical uncertainty.

1383

1384

1385

1386 1387 For the extracted single-differential cross sections, the statistical uncertainty  $\delta_{\text{stat}}^{\text{tot}}(\Delta X)$  (where X is one of the final state variables, *e.g.*  $M_{h_1h_2}$ ,  $\theta_{h_1}$ ,  $\alpha_{h_1}$ ) was obtained from the uncertainties  $\delta_{\text{stat}}^{\text{tot}}(\Delta^5 \tau)$  of the fivefold differential cross sections according to the standard error propagation rules.

### B. Model-dependent uncertainties

In studies of double-pion production off free protons, the cross section model dependence originates from the filling of the empty cells and the corresponding cross section uncertainty is commonly treated as a separate uncertainty type [15, 16, 33–37, 43]. In this analysis, one further source of the model dependence is the correction that unfolds the effects of the initial proton motion (see Sec. V C). The two sources were found to give comparable uncertainties for the two lowest W bins, while for the other bins the dominant part of the model-dependent uncertainty comes from the filling of the empty cells.

Both the contribution from the empty cells and the value of the unfolding correction vary greatly (from completely insignificant to considerable) for different bins in the final hadronic variables. Therefore, the model-dependent uncertainties were estimated in each  $\Delta X$  bin of the single-differential cross sections (where X is one of the final state variables introduced in Sec. IV C).

The absolute cross section uncertainty  $\delta_{\text{model}}^{\text{cells}}(\Delta X)$  <sup>1451</sup> due to the filling of the empty cells was calculated by <sup>1452</sup>

$$\delta_{\text{model}}^{\text{cells}}(\Delta X) = \frac{1}{2} \left( \left[ \frac{\mathrm{d}\sigma}{\mathrm{d}X} \right]_{\text{filled}} - \left[ \frac{\mathrm{d}\sigma}{\mathrm{d}X} \right]_{\text{not filled}} \right), \quad (23)^{1454}_{1455}$$

1453

1464

1471

1475

1476

1477

where the parentheses contain the difference between  $_{1457}$ the cross section values calculated with the empty  $_{1458}$ cell contributions ("filled") and without them ("not  $_{1459}$ filled"), see also Fig. 9.

<sup>1416</sup> For each  $\Delta X$  bin of the single-differential distribu-<sup>1417</sup> tions, the relative uncertainty due to the unfolding <sup>1462</sup> <sup>1418</sup> procedure was estimated by <sup>1463</sup>

$$\varepsilon_{\text{model}}^{\text{unfold}}(\Delta X) = \left| \frac{\left[\frac{\mathrm{d}\sigma}{\mathrm{d}X}\right]_{\text{folded}} - \left[\frac{\mathrm{d}\sigma}{\mathrm{d}X}\right]_{\text{unfolded}}}{\left[\frac{\mathrm{d}\sigma}{\mathrm{d}X}\right]_{\text{folded}} + \left[\frac{\mathrm{d}\sigma}{\mathrm{d}X}\right]_{\text{unfolded}}} \right|. \quad (24)^{1466}_{1467}$$

The corresponding absolute uncertainty is then 1469 given by 1470

$$\delta_{\text{model}}^{\text{unfold}}(\Delta X) = \left[\frac{\mathrm{d}\sigma_{\rm v}}{\mathrm{d}X}\right]_{\text{final}} \varepsilon_{\text{model}}^{\text{unfold}}.$$
 (25) <sup>1472</sup>
<sub>1473</sub>
<sub>1474</sub>

1419

# C. Systematic uncertainties

<sup>1420</sup> The systematic uncertainty of the extracted cross <sup>1478</sup> <sup>1421</sup> sections was estimated in each bin in W and  $Q^2$ . The <sup>1479</sup> <sup>1422</sup> following sources are considered to contribute to the <sup>1480</sup> <sup>1423</sup> total systematic uncertainty. <sup>1481</sup>

The presence of quasi-elastic events in the dataset 1482 1424 facilitates the verification of both the overall cross sec- 1483 1425 tion normalization and the quality of the electron se-1484 1426 lection. The former may lack accuracy due to poten-<sup>1485</sup> 1427 tial miscalibrations of the Faraday cup, fluctuations in 1486 1428 the target density, and imprecision knowledge of other 1487 1429 parameters involved in the luminosity calculation (see 1488 1430 1431 Eq. (10)). The quality of the electron selection in turn <sup>1489</sup> may suffer from potential miscalibrations of different <sup>1490</sup> 1432 detector parts, inaccuracies in the electron tracking <sup>1491</sup> 1433 and identification, and uncertainties of the cuts and 1492 1434 corrections involved in the electron selection. 1493 1435

To verify the cross section normalization and the 1494 1436 quality of the electron selection, the quasi-elastic cross 1495 1437 section was estimated and compared with the Bosted  $^{\ 1496}$ 1438 parameterization of the quasi-elastic cross section off 1497 1439 the deuteron [50, 51]. This comparison indicates a <sup>1498</sup> 1440 better than 5% agreement between the experimental <sup>1499</sup> 1441 and parameterized cross sections and, therefore, a 5%  $_{1500}$ 1442 global uncertainty was assigned to the extracted cross <sup>1501</sup> 1443 sections to account for potential inaccuracies in the 1502 1444 normalization and electron selection [28, 31]. 1503 1445

In this study, the cross sections were extracted <sup>1504</sup> in three sets of kinematic variables, as described in <sup>1505</sup> Sec. IV C. The fully integrated cross sections were <sup>1506</sup> found to slightly differ among the sets due to different <sup>1507</sup> data and efficiency propagation to various kinematic <sup>1508</sup> grids. As a final result, integral cross sections averaged (as arithmetic mean) over these three grids are reported and the standard error of the mean is interpreted as a systematic uncertainty [28, 31]. Since different variable sets correspond to different registered final hadrons (and, therefore, to different combinations of the hadron cuts), the uncertainty due to integration over the three sets of final hadronic variables includes uncertainties due to the shapes of the hadron cuts that were used in the analysis. The average value of this uncertainty among all W and  $Q^2$ bins is 1.6%.

The cut on the relative efficiency uncertainty performed in this study excludes entire kinematic cells from further consideration, and therefore reduces the total statistical uncertainty and increases the modeldependent uncertainty of the extracted cross sections. To achieve a compromise between these two effects, the cut value was set to 30% (see Sec. IV F). To estimate the systematic effect of this cut, the fully integrated cross sections were also calculated for the cut values 25% and 35%. As a final result, the arithmetic mean of the integral cross sections for these three cut values is reported, and the standard error of the mean is interpreted as a systematic uncertainty [28, 31]. The systematic effect of the relative efficiency uncertainty cut was estimated for each bin in W and  $Q^2$ individually and was found to be minor, *i.e.* the average uncertainty value is 0.8%.

One more part of the systematic uncertainties comes from the effective correction due to FSIbackground admixture. This correction was performed for the experimental events in the  $\pi^-$  missing topology as described in Sec. III E 3. The fit shown in Fig. 7 (as well as the corresponding correction factor given by Eq. (5)) was found to be slightly dependent on the histogram binning. To account for this uncertainty, the correction factor was calculated for five different histogram bin sizes, and the arithmetic mean of these five individual values was used for the correction (for each bin in W). The absolute uncertainty of the resulting correction factor was calculated as the standard error of the mean. The corresponding cross section uncertainty was estimated according to the standard error propagation rules [28, 31]. The systematic effect of the FSI-background correction was estimated for each bin in W and  $Q^2$  where the correction was applied. For such bins, the average value of the relative systematic uncertainty is 0.4%.

As a common practice in studies of the double-pion cross sections with CLAS [15, 16, 33–37, 43], a 5% global uncertainty was assigned to the cross section due to the inclusive radiative correction procedure (see Sec. V B).

The uncertainties due to these sources were summed up in quadrature in each W and  $Q^2$  bin to obtain the total systematic uncertainty for the fully integrated cross sections. The common value of the total relative systematic uncertainty  $\varepsilon_{\rm sys}^{\rm tot}$  is around 7% 1545 (it is, however, higher near the threshold).

### 1511 D. Summary for the cross section uncertainties 1548

Finally, the model-dependent uncertainties <sup>1550</sup>  $\delta_{\text{model}}^{\text{cells}}(\Delta X)$  and  $\delta_{\text{model}}^{\text{unfold}}(\Delta X)$  defined by Eq. (23) and <sup>1551</sup> Eq. (25), respectively, were combined with the total <sup>1552</sup> statistical uncertainty  $\delta_{\text{stat}}^{\text{tot}}(\Delta X)$  defined in Sec. VI A <sup>1553</sup> as follows, <sup>1554</sup>

1547

1549

1579

1580

1581

1582

1583 1584

1592

1593

$$\delta_{\text{stat,mod}}^{\text{tot}}(\Delta X) = \sqrt{\left(\delta_{\text{stat}}^{\text{tot}}\right)^2 + \left(\delta_{\text{model}}^{\text{cells}}\right)^2 + \left(\delta_{\text{model}}^{\text{unfold}}\right)^2}_{(26)} \frac{1556}{1557}$$

The extracted cross sections are reported with the 1512 1550 uncertainty  $\delta_{\text{stat,mod}}^{\text{tot}}$ , which for the single-differential 1513 1560 distributions is given by Eq. (26). For the fully in-tegrated cross sections,  $\delta_{\rm stat,mod}^{\rm tot}$  is obtained from the 1562 1514 1515 uncertainty of the single-differential distributions ac-1516 cording to the standard error propagation rules. For  $_{\scriptscriptstyle 1564}$ 1517 the majority of integral  $(W, Q^2)$  points, the uncer-1518 tainty  $\delta_{\text{stat,mod}}^{\text{tot}}$  stays on a level of 4%-6%. 1519 1566

For the fully integrated cross sections, in addition to the uncertainty  $\delta_{\text{stat,mod}}^{\text{tot}}$ , the total systematic uncertainty is also reported as a separate quantity. If necessary, the relative systematic uncertainty ( $\varepsilon_{\text{sys}}^{\text{tot}}$ ) in each W and  $Q^2$  bin can be propagated as a global factor to the corresponding single-differential distributions.

In this study, the uncertainty  $\delta^{\rm tot}_{\rm stat,mod}$  is less than  $_{1571}$ 1526 the total systematic uncertainty for the majority of 1527  $(W,Q^2)$  points, exceeding it only for  $W \lesssim 1.4$  GeV. 1528 This is because the former rises near the threshold due 1529 to small experimental statistics, large contribution of  $_{1574}$ 1530 the empty cells (see Sec. VA), and pronounced impact 1531 1575 of the unfolding correction (see Sec. VC). 1532 1576

<sup>1533</sup> The extracted cross sections with their estimated <sup>1577</sup> <sup>1534</sup> uncertainties are presented in Sec. VIII. <sup>1578</sup>

# 1535 VII. FINAL STATE INTERACTIONS

A. FSIs for  $\gamma_v p(n) \to p'(n') \pi^+ \pi^-$ 

Hadrons produced in exclusive reactions are subject
to final state interactions (FSIs). The nature of this
phenomenon is complicated due to numerous mechanisms being involved, most of which are driven by the
strong interaction [52, 53].

<sup>1542</sup> For reactions occurring off nucleons contained in <sup>1590</sup> <sup>1543</sup> nuclei, one can separate FSIs into two general types: <sup>1591</sup>

# • interactions among the final hadrons<sup>3</sup> and

• interaction of the final hadrons with the spectator nucleon<sup>4</sup>.

Both FSI types can involve simple momentum exchanges between the hadrons, as well as far more complicated processes, such as nucleon resonance excitations or charge exchange.

Clearly, FSIs in conventional reactions off free protons are limited to the first type.

The reaction final hadrons are produced in one vertex and after the production, they fly apart in radial directions. The spectator neutron, which was not involved in the production of the final hadrons, is located aside from the production vertex, so that the final hadrons can scatter off the neutron. Therefore, for the double-pion production off protons bound in deuterium, FSIs with the spectator correspond to a combination of proton-neutron [54, 55] and pion-neutron scattering [56–58], and thus represent a superposition of a broad spectrum of mechanisms inherent for these two scattering types.

Due to the relatively low energy of the final hadrons in this experiment, the majority of FSIs in the investigated reaction are thought to happen elastically, which implies that the quantum numbers of the participating hadrons do not change and no new particles are produced in such interactions [54].

### B. Distortions due to FSIs

The two FSI types introduced above have some kinematical distinctions from each other and their impact on the extracted cross sections also differ.

First, it is important that FSIs among the final hadrons preserve the total four-momentum of all three final hadrons and, therefore, do not alter missing mass distributions as long as no new particles are produced in these interactions [31]. However, FSIs among the final hadrons still affect the momenta of the individual particles, and thus introduce distortions into the measured cross sections (no matter whether off a free or bound nucleon). These cross section distortions can hardly be avoided on the level of the experimental data analysis due to the insensitivity of the missing mass distributions to this FSI type. This issue needs to be accounted for at the level of theoretical/phenomenological cross section interpretation.

Meanwhile, FSIs with the spectator nucleon have one distinctive difference from FSIs among the final hadrons. Specifically, as the spectator nucleon is extrinsic to the original exclusive reaction, any interaction with it changes the total four-momentum of

 $<sup>^3</sup>$  Here the term "final hadrons" denotes  $p',\,\pi^+,\,{\rm and}\,\pi^-,\,{\rm which}$  define the reaction final state.

<sup>&</sup>lt;sup>4</sup> Here the term "spectator" denotes the neutron, which is the spectator of the original exclusive reaction.

the reaction final state. As a consequence, events in which final hadrons interacted with the spectator, introduce distortions into missing mass distributions [41]. These distortions are associated with the specta-

tions [41]. These distortions reveal agglomerations of
FSI-affected events, which allows for their separation
from the quasi-free event sample, so that the quasifree cross sections can be extracted (see more details
in Sec. III E).

In this analysis, distortions due to FSIs with the 1602 spectator neutron are clearly visible in experimen-1603 tal distributions of the missing quantities  $P_X$  and 1604  $M^2_{X[\pi^-]}$ , where the former is defined by Eq.(2) and the 1605 latter is  $[P_{X[\pi^-]}^{\mu}]^2$  with the  $P_{X[\pi^-]}^{\mu}$  defined by Eq.(3). 1606 These distortions were found to differ in different re-1607 gions of the reaction phase space and also to be topol-1608 ogy dependent. Illustrations and further details are 1609 given in the following subsections. 1610

# <sup>1611</sup> C. Comparison between the two topologies

Figure 11 presents the  $M^2_{X[\pi^-]}$  distributions for 1612 the fully exclusive (left) and the  $\pi^-$  missing (right) 1613 topologies in five 100-MeV-wide bins in W. Experi-1614 mental FSI-affected distributions are shown in black, 1615 1616 while blue histograms correspond to simulated distributions of pure quasi-free events. The mismatch be-1617 tween them therefore reveals agglomerations of events 1618 in which the final hadron interacted with the specta-1619 tor neutron. The Monte Carlo simulation was per-1620 formed on the basis of the TWOPEG-D event gen-1621 erator [25], which successfully reproduces the Fermi 1622 smearing of the missing quantities, but does not in-1623 clude FSI effects. The distributions are normalized 1624 in a way that the peak maxima are equal to one and 1625 then zoomed in on the range [0, 0.25] on the y-axis, 1626 to better visualize the mismatch. 1627

Final hadrons attributed to various topologies have different kinematics and therefore different probabilities to interact with the spectator neutron. For this reason, events affected by FSIs with the spectator are distributed differently in the two reaction topologies as illustrated by Fig. 11. More details can be found in Ref. [31].

1595

1596

# D. FSIs in the fully exclusive topology

To better understand the redistribution of events <sup>1645</sup> with FSIs in the fully exclusive topology, experimen-<sup>1646</sup> tal  $P_X$  and  $M_{X[\pi^-]}^2$  distributions were examined in <sup>1647</sup> different slices of the final hadron momentum magni-<sup>1648</sup> tudes and polar angles (in the Lab system).<sup>1649</sup>

<sup>1641</sup> In general, the proportion of events affected by FSIs <sup>1650</sup> <sup>1642</sup> with the spectator was found to vary greatly (from <sup>1651</sup> <sup>1643</sup> negligible to considerable) in different ranges of final <sup>1652</sup> <sup>1644</sup> hadron momenta/angles. <sup>1653</sup>

FIG. 11.  $M_{X[\pi^-]}^2$  distributions for the fully exclusive (left) and for the  $\pi^-$  missing (right) topologies in five 100-MeVwide bins in W. The mismatch between the experimental (black) and the simulated (blue) histograms reveals agglomerations of events in which the final hadron interacted with the spectator neutron. The distributions are normalized in a way that the peak maxima are equal to one and then zoomed in on the range [0, 0.25] on the y-axis, to better visualize the mismatch. The presented statistics correspond to the unzoomed experimental distributions.

Remarkably, some regions of the reaction phase space were found to be completely dominated by quasi-free events. For example, Fig. 12 shows a good match between the experimental (black) and the simulated (blue) distributions of the quantities  $P_X$  (left) and  $M_{X[\pi^-]}^2$  (right) for  $\pi^-$  momentum magnitudes from 0.5 GeV to 1.4 GeV, which indicates the dominance of quasi-free events in this momentum range.

Conversely, other regions of the reaction phase

FIG. 12. Experimental (black) and simulated (blue) distributions of the quantities  $P_X$  (left) and  $M^2_{X[\pi^-]}$  (right) for the  $\pi^-$  momentum magnitude ranging from 0.5 to 1.4 GeV. The distributions are plotted for the fully exclusive topology and normalized in a way that the maxima of the main peaks are equal to one.

FIG. 13. Experimental (black) and simulated (blue) dis-<sup>1697</sup> tributions of the quantities  $P_X$  (left) and  $M^2_{X[\pi^-]}$  (right) <sup>1698</sup> for the proton polar angle ranging from 40° to 60°. The <sup>1699</sup> distributions are plotted for the fully exclusive topology <sup>1700</sup> and normalized in a way that the maxima of the main peaks are equal to one.

space were revealed to be mostly populated by events 1654 1703 with FSI-disturbed kinematics. Figure 13 illustrates 1655 1704 this effect for proton polar angles ranging from  $40^{\circ}$ 1656 1705 to  $60^{\circ}$ , where a large mismatch between the experi-1657 1706 mental (black) and the simulated (blue) distributions 1658 1707 is observed, which reveals a considerable fraction of 1659 1708 events affected by FSI with the spectator in this kine-1660 1709 matic region. More illustrations can be found in 1661 1710 Ref. [31]. 1662 1711

### 1663 E. FSIs in topologies with a missing hadron

In topologies with an unregistered hadron i, the quantity  $M_{X[i]}^2$  is typically used for the channel identification. For reactions occurring off bound nucleons, interactions between the final hadrons and the spectator nucleon have a different impact on  $M_{X[i]}^2$  depending on which final hadron experienced the FSI.

<sup>1670</sup> In general, the following three possibilities can be <sup>1722</sup> <sup>1671</sup> distinguished for events from the topologies with an <sup>1723</sup>

unregistered hadron for reactions off a proton bound in deuterium (assuming that at most one final hadron in an event interacted with the neutron).

- 1. All final hadrons in an event avoided interactions with the neutron. Then this event is a true quasi-free event and the four-momentum of the unregistered hadron can be successfully reconstructed as missing.
- 2. The unregistered hadron avoided FSIs, while one of the registered hadrons interacted with the neutron, changing its four-momentum and hence losing its kinematic affiliation to the initial reaction. This does not allow for proper reconstruction of the missing hadron fourmomentum, causing the event to contribute to the FSI-background in the  $M_{X[i]}^2$  distributions [41].
- 3. The unregistered hadron interacted with the neutron and the registered hadrons did not. In this case, the missing four-momentum of the unregistered hadron corresponds to its fourmomentum before the FSI. Such an event then kinematically mimics a quasi-free event.

This disposition reveals that for reactions off bound nucleons, topologies with a missing hadron suffer from the presence of falsely defined quasi-free events, which are events of the third type. Such events are kinematically indistinguishable from true quasi-free events and for this reason this effect can hardly be corrected for.

# VIII. EXTRACTED QUASI-FREE CROSS SECTIONS

In Fig. 14, the W dependence of the extracted fully integrated cross sections of the reaction  $\gamma_v p(n) \rightarrow$  $p'(n')\pi^+\pi^-$  is shown by the black filled circles for twelve analyzed  $Q^2$  bins. For each point, the pink shadowed area is the total cross section uncertainty, which is the uncertainty  $\delta_{\text{stat,mod}}^{\text{tot}}$  (see Sec. VID) summed up in quadrature with the total systematic uncertainty (see Sec. VIC). The error bars correspond to the  $\delta_{\text{stat,mod}}^{\text{tot}}$  uncertainty only.

For each integral cross section point, a set of nine single-differential cross sections was obtained (as described in Sec. IVE). As a typical example, Figure 15 presents the single-differential cross sections for W = 1.5375 GeV and  $Q^2 = 0.625$  GeV<sup>2</sup>. The cross sections are reported with the uncertainty  $\delta_{\text{stat,mod}}^{\text{tot}}$ shown by the error bars. The full set of extracted single-differential cross sections is available in the CLAS physics database [5] and also on GitHub [59].

The extracted cross sections are quasi-free, meaning that the contribution from events in which the final hadrons interacted with the spectator neutron

FIG. 14. W dependences of the fully integrated cross sections in various bins in  $Q^2$ . The pink shadowed areas show the total cross section uncertainty, which is the uncertainty  $\delta_{\text{stat,mod}}^{\text{tot}}$  (see Sec. VID) summed up in quadrature with the total systematic uncertainty (see Sec. VIC). The error bars correspond to the  $\delta_{\text{stat,mod}}^{\text{tot}}$  uncertainty only. The cross section estimation shown by the solid curves is based on the free proton event generator TWOPEG [39] (see text for more details).

is reduced to the kinematically achievable minimum. 1746
The cross sections, however, are still convoluted 1747
with effects of FSIs among the final hadrons, which 1748
is like conventional free proton cross sections (see 1749
Sec. VIIB). Also note that in this study, the initial 1750
proton is assumed to be on-shell. 1751

In general, the admixture of the FSI-background 1752 1730 left after the exclusivity cut in the  $\pi^-$  missing topol- 1753 1731 ogy may potentially affect the shape of the extracted 1754 1732 single-differential distributions as it was corrected 1755 1733 only in an integral sense (as described in Sec. III  $\ge 3$ ). 1756 1734 However, as this admixture is present only for events 1757 1735 from the  $\pi^-$  missing topology for W > 1.45 GeV <sub>1758</sub> 1736 and stays there at a level of 3%-7%, its impact is 1759 1737 not thought to be discernible against the total cross 1760 1738 section uncertainty. 1739 1761

One more potential uncertainty source for the ex-  $_{1762}$ tracted quasi-free cross sections is the presence of  $_{1763}$ falsely identified quasi-free events in the  $\pi^-$  missing  $_{1764}$ topology. Unfortunately, as true quasi-free events are  $_{1765}$ kinematically identical to those that are falsely identi-  $_{1765}$ fied, no corresponding correction to the cross section  $_{1767}$  can be developed (see Sec. VII E for details).

The solid curves in Figs. 14 and 15 correspond to the cross section estimation performed by means of TWOPEG [39], which is the event generator for double-pion electroproduction off free protons. This event generator currently provides the best estimation of the free proton cross sections in the investigated kinematic region.

The cross section approximation implemented into the TWOPEG event generator is based on the mesonbaryon reaction model JM [12–14]. The generator employs the five-differential structure functions from the recent version of the JM model fit to the existing CLAS results on double-pion photo- and electroproduction off free protons [13, 34, 36, 48]. In the kinematic areas already covered by the CLAS data, TWOPEG performs the interpolation of the model structure functions and successfully reproduces the available fully integrated and single-differential cross sections. In the areas not yet covered by the CLAS data, special extrapolation procedures were applied that included additional world data on the fully inte-

150

grated photoproduction cross sections [60, 61]. 1787 1768 For the purpose of this comparison, the cross sec- 1788 1769 tion distributions obtained by TWOPEG were nor- 1789 1770 malized to integrally match the quasi-free cross sec- 1790 1771 tions extracted in this study. 1772

150

Figures 14 and 15 indicate that apart from the over- 1792 1773 all integral scaling, the free proton cross sections may 1793 1774 serve as an adequate zeroth-order approximation for 1794 1775 the quasi-free cross sections off protons in deuterium. 1795 1776 More elaborate insight into the interpretation of the 1796 1777 extracted quasi-free cross sections is given in the next 1797 1778 section, which presents their comparison with the free 1798 1779 proton measurements from Refs. [15, 16]. 1799 1780

#### IX. COMPARISON WITH THE FREE 1781 PROTON MEASUREMENTS 1782

This study benefits from the fact that the cross sec- 1805 1783 tions of the same exclusive reaction off free protons 1806 1784 have been recently extracted from CLAS data [15, 16]. <sup>1807</sup> 1785 These free proton measurements were performed un- 1808 1786

der the same experimental conditions as in this study. including the beam energy value and the target setup. For the majority of integral  $(W, Q^2)$  points, the statistical uncertainty combined with the model-dependent uncertainty is at a level of 1%-3% for the free proton cross sections and at a level of 4%-6% for the cross sections obtained in this study. Both measurements have identical binning in all kinematic variables and similar inherent systematic inaccuracies. Therefore, a direct comparison of the cross sections extracted in this study with their free proton counterparts from Refs. [15, 16] provides the experimentally best possible opportunity to explore distinctions between the  $\pi^+\pi^-$  electroproduction off protons in deuterium and the corresponding reaction off free protons.

This section compares the two cross section sets and examines the difference between them over the entire reaction phase space. In this investigation, only the statistical and model-dependent uncertainties of the two measurements were considered, while the systematic effects were assumed to cancel out.

Figure 16 presents the ratio of the fully integrated

FIG. 16. Ratio of the fully integrated quasi-free cross sections obtained in this study over the free proton cross sections from Refs. [15, 16]. The red curves correspond to the polynomial fit. The dashed line marks the value of 0.75.

1809quasi-free cross sections obtained in this study over18331810the free proton cross sections of Refs. [15, 16]. The18341811ratio was fit with a fourth-order polynomial. The18351812dashed line marks the value of 0.75.1836

As seen in Fig. 16, the ratio of the two cross section 1837 sets demonstrates a modest W dependence with an 1838 average level of 70%-75%, appearing to drop slightly 1839 near the threshold, as well as in the dip region between 1840 the two integral resonance peaks. 1841

Figure 17 shows the ratio of the invariant mass 1842 1818 distributions from this study and the free proton 1843 1819 study [15, 16]. Rows from top to bottom correspond 1844 1820 to  $M_{p'\pi^+}$ ,  $M_{\pi^+\pi^-}$ , and  $M_{\pi^-p'}$ , respectively. The ra- 1845 1821 tios were obtained individually for each  $(W, Q^2)$  point 1846 1822 and then averaged over  $Q^2$  to decrease the resulting 1847 1823 uncertainties. The kinematic broadening of the invari-1824 ant mass distributions with W (illustrated by Eq. (8) 1849 1825 in Sec. IVD) and the consequent nonidentical distri-1826 bution of data points in different W bins does not 1851 1827 allow for further averaging over W. The red curves 1852 1828 correspond to the fit with a fourth-order polynomial 1853 1829 and the dashed line marks the value of 0.75. 1830

As seen in Fig. 17, the cross section ratio demon-<sup>1855</sup> strates different consistent patterns for the three in-<sup>1856</sup> variant mass distributions. For  $M_{p'\pi^+}$  (top row), it gives a rise near the left distribution edge, then gradually drops towards the right edge, featuring a small plateau in the middle. For  $M_{\pi^+\pi^-}$  (middle row), the situation is different, *i.e.* the cross section ratio shows a pronounced drop of up to ~40% at the left edge, then rises abruptly up to ~75% and stays on this constant level further on. For the third invariant mass,  $M_{\pi^-p'}$  (bottom row), the ratio continuously and almost linearly grows from ~60% at the left edge to ~100% at the right.

Figure 18 presents the ratio of the angular distributions from this study and the free proton study [15, 16]. The first row shows the  $\theta_{p'}$ ,  $\theta_{\pi^-}$ , and  $\theta_{\pi^+}$  distributions, while the second row shows the  $\alpha_{p'}$ ,  $\alpha_{\pi^-}$ , and  $\alpha_{\pi^+}$  distributions, respectively. The ratios were obtained individually for each  $(W, Q^2)$  point and then averaged over W and  $Q^2$  to minimize the resulting uncertainties. The red curves correspond to polynomial fits and the dashed line marks the value of 0.75.

As seen in Fig. 18, the behavior of the cross section ratio differs for various angular distributions. Its dependence on hadron polar angles appears to be of the most interest. For  $\theta_{p'}$  (top left plot), the ratio

FIG. 17. Ratio of the invariant mass distributions obtained in this study over their free proton analogues from Refs. [15, 16]. Rows from top to bottom correspond to  $M_{p'\pi^+}$ ,  $M_{\pi^+\pi^-}$ , and  $M_{\pi^-p'}$ , respectively. The ratios were averaged over  $Q^2$  to decrease the resulting uncertainties. The red curves correspond to polynomial fits. The dashed line marks the value of 0.75.

FIG. 18. Ratio of the angular distributions from this study over their free proton analogues from Refs. [15, 16]. The first row shows the  $\theta_{p'}$ ,  $\theta_{\pi^-}$ , and  $\theta_{\pi^+}$  distributions, while the second row shows the  $\alpha_{p'}$ ,  $\alpha_{\pi^-}$ , and  $\alpha_{\pi^+}$  distributions, respectively. The ratios were averaged over W and  $Q^2$  to minimize the resulting uncertainties. The red curves correspond to polynomial fits. The dashed line marks the value of 0.75.

starts from  $\sim 70\%$  at small angles, grows up to  $\sim 75\%$  1912 1857 at 50°, and further stays on a distinct plateau up to 1913 1858  $120^{\circ}$ , showing then a mild rise up to  $\sim 80\%$  at back- 1914 1859 ward angles. For  $\theta_{\pi^-}$  (top middle plot), the ratio stays 1915 1860 at  $\sim 75\%$  at small angles, then grows up to  $\sim 80\%$  giv-1861 ing a broad peak at around  $100^{\circ}$ , and drops down to  $_{1917}$ 1862  $\sim$ 70% at backward angles. For the third polar angle 1918 1863  $(\theta_{\pi^+})$ , the ratio value maintains on the level of ~75% <sub>1919</sub> 1864 all the way through around  $120^{\circ}$ , then peaks up to 1920 1865 more than 80% at 150°, and finally shows a steep  $_{1921}$ 1866 drop. 1867 1922

Note that the conventional free proton cross sec- 1923 1868 tions represent all reaction events, while the cross sec- 1924 1869 tions extracted in this study are quasi-free (up to the 1925 1870 accuracy with which quasi-free events can be kine- 1926 1871 matically isolated) and hence do not include contri-1872 butions from events in which final hadrons interacted 1928 1873 with the spectator neutron. The latter events there-1874 fore are mainly responsible for the difference between 1930 1875 the two cross section sets. 1876 1931

Therefore, the performed comparison allows us to 1932 1877 estimate the proportion of events affected by FSIs 1933 1878 with the spectator neutron for the reaction off pro-1934 1879 tons in deuterium. From Figs. 16, 17, and 18, one 1935 1880 can conclude that the contribution from such events 1936 1881 to the total number of the reaction events varies from 1937 1882  ${\sim}60\%$  to a few percent in different regions of the re-  $_{\scriptscriptstyle 1938}$ 1883 action phase space. However, for the most part of the 1939 1884 phase space, one can estimate the contribution from  $_{\scriptscriptstyle 1940}$ 1885 events affected by FSIs with the spectator to be on a 1886 level of  $\sim 25\%$ . 1887

Meanwhile, a small part of the difference between 1943 1888 the two cross section sets may come from other 1944 1889 sources, as for example from possible modifications 1945 1890 of nucleons and their excited states inside the nuclear  $_{1946}$ 1891 medium [6–8, 17, 18]. To make any conclusions on this 1892 10/7 matter, a further more comprehensive investigation is  $_{1948}$ 1893 needed, which should employ a theoretical interpreta-1894 1940 tion of the obtained cross section ratios. 1895 1950

1896

# X. CONCLUSIONS

1951

1952

1953

1954

This paper reports the results of the experimental 1955 data analysis for the process of charged double-pion 1956 electroproduction off protons bound in deuterium. 1957

The fully integrated and single-differential cross 1900 sections of the reaction  $\gamma_v p(n) \to p'(n') \pi^+ \pi^-$  have 1901 1958 been obtained for the first time. The measurements 1902 were performed in the kinematic region of the 1903 invariant mass W from 1.3 GeV to 1.825 GeV and 1959 1904 photon virtuality  $Q^2$  from 0.4 GeV<sup>2</sup> to 1.0 GeV<sup>2</sup>. 1960 1905 The results benefit from fine binning in all kinematic 1961 1906 variables, small statistical uncertainties, and modest 1962 1907 model dependence. The extracted cross sections are 1963 1908 quasi-free, meaning that the admixture of events in 1964 1909 which the final hadrons interacted with the spectator 1965 1910 neutron is reduced to the kinematically achievable 1966 1911

minimum. The whole set of the obtained cross sections is available in the CLAS physics database [5] and also on GitHub [59].

Due to the Fermi motion that initial protons undergo in deuterium nuclei, this study encountered a set of peculiarities, which were not relevant for free proton studies. Effects of the initial proton motion turned out to be intertwined with many analysis aspects: they lead to the smearing of some kinematic quantities, alter the common procedure of the Lab to CMS transformation, cause the need to perform an unfolding correction to the extracted cross sections, and more [25, 28, 31]. To deal with these issues, special methods and techniques were developed, which go beyond the conventional analysis framework elaborated in previous free proton studies [15, 16, 33–37, 43, 48].

Interactions of the reaction final hadrons with the spectator nucleon represent another peculiar aspect of this analysis. These interactions introduce distortions into distributions of some kinematic quantities (such as missing masses) thus complicating the exclusive event selection. FSI effects have been found to differ depending on the reaction topology due to nonidentical geometrical acceptance of the topologies in CLAS. For this study, isolation of quasi-free events from the FSI-background was performed in each topology individually according to the specially developed procedures.

The paper also presents the comparison of the obtained cross sections with the corresponding free proton cross sections recently extracted from CLAS data [15, 16]. Assuming that the difference between the two cross section sets mostly originates from events in which FSIs between the final hadrons and the spectator neutron took place, this comparison allowed us to make an estimate of the contribution from such events to the total number of reaction events. For the most part of the reaction phase space, the contribution from events affected by FSIs with the spectator was found to be around 25%. This comparison also opens an opportunity to explore other potential reasons that may contribute to the difference between the cross section sets, which includes possible in-medium modifications of properties of nucleons and their excited states [6–8, 17, 18].

## ACKNOWLEDGMENTS

The authors thank the technical staff at Jefferson Lab and at all the participating institutions for their invaluable contributions to the success of the experiment. This work was supported in part by the National Science Foundation (NSF) under Grant No. PHY 10011349, Jefferson Science Associates (JSA), the U.S. Department of Energy (DOE) under Contract No. DE-AC05-06OR23177, University 1967of South Carolina (USC), the Skobeltsyn Institute 1973tre1968of Nuclear Physics (SINP), the Physics Department 1974Free1969at Lomonosov Moscow State University (MSU), Ohio 1975the1970University (OU), the Chilean Agencia Nacional de In- 1976the1971vestigacion y Desarrollo (ANID), the Italian Istituto 1977and1972Nazionale di Fisica Nucleare (INFN), the French Cen- 1978cil
